## Abstract

We identify a ‘slope’ factor in exchange rates. High interest rate currencies load more on this slope factor than low interest rate currencies. This factor accounts for most of the cross-sectional variation in average excess returns between high and low interest rate currencies. A standard, no-arbitrage model of interest rates with two factors – a country-specific factor and a global factor – can replicate these findings, provided there is sufficient heterogeneity in exposure to global or common innovations. We show that our slope factor identifies these common shocks, and we provide empirical evidence that it is related to changes in global equity market volatility. By investing in high interest rate currencies and borrowing in low interest rate currencies, US investors load up on global risk.

*JEL: G12, G15, F31.*

We show that the large co-movement among exchange rates of different currencies supports a risk-based view of exchange rate determination. In order to do so, we start by identifying a slope factor in exchange rate changes: the exchange rates of high interest rate currencies load positively on this factor, while those of low interest rate currencies load negatively on it. The covariation with this slope factor accounts for most of the spread in average returns between baskets of high and low interest rate currencies – the returns on the currency carry trade. We show that a no-arbitrage model of interest rates and exchange rates with two state variables – a country-specific and a global risk factors – can match the data provided there is sufficient heterogeneity in countries' exposures to the global risk factor. To support this global risk interpretation, we provide evidence that the global risk factor is closely related to changes in volatility of equity markets around the world.

We identify this common risk factor in the data by building monthly portfolios of currencies sorted by their forward discounts. The first portfolio contains the lowest interest rate currencies while the last contains the highest. The first two principal components of the currency portfolio returns account for most of the time series variation in currency returns. The first principal component is a level factor. It is essentially the average excess return on all foreign currency portfolios. We call this average excess return the dollar risk factor  $RX$ . The second principal component is a slope factor whose weights decreases monotonically from positive to negative from high to low interest rate currency portfolios. Hence, average returns on the currency portfolios line up with portfolio loadings on this second component. This slope factor is very similar to the return on a zero-cost strategy that goes long in the last portfolio and short in the first portfolio. We label this excess return the carry trade risk factor  $HML_{FX}$ , for high minus low interest rate currencies. We obtain the same results for exchange rate changes as for currency returns. Our paper is the first to document the common factor in exchange rates sorted by interest rates, which is the key ingredient in a risk-based explanation of carry trade returns.

In international finance, there is a large literature that studies asset pricing in integrated capital markets.<sup>1</sup> In this class of integrated capital market models, risk refers invariably to exposure to some common or global factor. We show that the slope factor in exchange rates provides a direct

measure of the global risk factor. This factor, which was constructed from currency portfolios, explains variation in the country-level returns as well, and the estimated risk prices are very similar to those obtained from the currency portfolios. We explain about two thirds of the cross-sectional variation when we allow for time-variation in the betas of individual currencies with our factors, which is captured by variation in relative interest rates.

Building on our empirical findings, we derive conditions that candidate stochastic discount factors need to satisfy in order to match our currency portfolio returns. Our results refine the conditions derived by Backus, Foresi and Telmer (2001) for replicating the forward premium anomaly in a large class of exponentially affine asset pricing models.<sup>2</sup> Heterogeneity in exposure to country-specific risk can generate negative UIP slope coefficients for individual currency pairs, as pointed out by Backus et al. (2001), but it cannot explain the cross-section of carry trade returns. The intuition is simple. Investors earn the carry trade premium by shorting baskets of low interest rate currencies and going long in baskets of high interest rate currencies. Provided that they invest in large baskets of currencies, carry trade investors are not exposed to any country-specific risk.

We show that heterogeneity in exposure to common risk can both explain the carry trade returns and deliver the negative UIP slope coefficients.<sup>3</sup> First, we need a large common or global component in the pricing kernel, because this is the only source of cross-sectional variation in currency risk premia. Second, we need sufficient heterogeneity in exposure to the common component: currencies with currently (on average) lower interest rates need to be temporarily (permanently) more exposed to the common component. Affine asset pricing models automatically satisfy the second condition provided that an increase in the conditional volatility of the pricing kernel lowers the short term interest rate. These two conditions ensure the existence of currency risk premia and carry trade excess returns from the perspective of *all* investors, regardless of the home currency. Currency risk premia are determined by a home risk premium that compensates for home country risk (e.g. a dollar risk premium for the US investor) and a carry trade risk premium that compensates for global or common risk.

Without exposure to common risk, the carry risk premium is zero as shorting baskets of low

interest rate currencies and going long in baskets of high interest rate currencies does not expose investors to any country-specific or currency-specific risk. Temporary heterogeneity in exposure to common risk matches the conditional deviations from UIP; currencies with currently high interest rates deliver higher returns. Permanent differences in exposure to common risk match the unconditional deviations from UIP; currencies with on average high interest rates also deliver higher returns. These unconditional deviations from UIP in the cross-section account for 40% of the total carry trade risk premium. In the data, we find that a measure of global equity volatility accounts for the cross-section of carry trade returns, as predicted by the model. High (low) interest rate currencies tend to depreciate (appreciate) when global equity volatility is high.

Many papers have documented the failure of UIP in the time series, starting with the work of Hansen and Hodrick (1980) and Fama (1984): higher than usual interest rates lead to further appreciation, and investors earn more by holding bonds in currencies with interest rates that are *higher than usual*.<sup>4</sup> By building portfolios of positions in currency forward contracts sorted by forward discounts, Lustig and Verdelhan (2005, 2007) have shown that UIP fails in the cross-section, even when including developing currencies: investors earn large excess returns simply by holding bonds from currencies with interest rates that are *currently high*, i.e. currently higher than those of other currencies, not only *higher than usual*, i.e. higher than usual for that same currency. Lustig and Verdelhan (2007) adopt the perspective of a US investor and test this investor's Euler equation. Our paper enforces the Euler equation of all investors. Furthermore, we distinguish between unconditional deviations and conditional deviations from UIP.

An alternative explanation of our findings is that the interest rate is simply one of the characteristics that determines returns as suggested by Bansal and Dahlquist (2000).<sup>5</sup> Rinaldo and Soderlind (2010), for example, pursue this further by arguing that some currencies are viewed simply as safe havens and therefore earn a lower risk premium than others that are perceived as more risky. Based on the empirical evidence, we cannot definitively rule out a characteristics-based explanation. Interest rates and slope factor betas are very highly correlated in the data. However, we replicate these findings in the data simulated from a version of our model that is calibrated to

match exchange rate and interest rate moments in the actual data. In the model-generated data, we cannot rule out a characteristics-based explanation either, even though the true data generating process has no priced characteristics.

Our paper is organized as follows: we start by describing the data, the method used to build currency portfolios, and the main characteristics of these portfolios. Section 2 shows that a single factor,  $HML_{FX}$ , explains most of the cross-sectional variation in foreign currency excess returns. Section 3 considers several extensions. We look at beta-sorted portfolios and confirm the same pattern in excess returns. By randomly splitting the sample, we also show that risk factors constructed from currencies not used as test assets still explain the cross-section. Finally, we show our results continue to hold at the country-level. In section 4, we use a no-arbitrage model of exchange rates to interpret these findings. A calibrated version of the model replicates the key moments of the data. Finally, we show that an equity-based volatility measure accounts for the cross-section of currency excess returns, as predicted by the model. Section 5 concludes. A separate appendix available online reports additional robustness checks. The portfolio data can be downloaded from our web sites and are regularly updated.

## 1 Currency Portfolios

We focus on investments in forward and spot currency markets. Compared to Treasury Bill markets, forward currency markets only exist for a limited set of currencies and shorter time-periods. But forward currency markets offer two distinct advantages. First, the carry trade is easy to implement in these markets, and the data on bid-ask spreads for forward currency markets are readily available. This is not the case for most foreign fixed income markets. Second, these forward contracts are subject to minimal default and counter-party risk. This section describes the properties of monthly foreign currency excess returns from the perspective of a US investor. We consider currency portfolios that include developed and emerging market countries for which forward contracts are traded. We find that currency markets offer Sharpe ratios comparable to the ones measured in equity markets, even after controlling for bid-ask spreads. As in Lustig and

Verdelhan (2005, 2007), we sort currencies on their interest rates and allocate them to portfolios. Unlike those papers, which use T-bill yields to compute annual currency excess returns, our current paper focusses on monthly investment horizons and uses only spot and forward exchange rates to compute returns.

## 1.1 Building Currency Portfolios

**Currency Excess Returns** We use  $s$  to denote the log of the spot exchange rate in units of foreign currency per US dollar, and  $f$  for the log of the forward exchange rate, also in units of foreign currency per US dollar. An increase in  $s$  means an appreciation of the home currency. The log excess return  $rx$  on buying a foreign currency in the forward market and then selling it in the spot market after one month is simply:

$$rx_{t+1} = f_t - s_{t+1}.$$

This excess return can also be stated as the log forward discount minus the change in the spot rate:  $rx_{t+1} = f_t - s_t - \Delta s_{t+1}$ . In normal conditions, forward rates satisfy the covered interest rate parity condition; the forward discount is equal to the interest rate differential:  $f_t - s_t \approx i_t^* - i_t$ , where  $i^*$  and  $i$  denote the foreign and domestic nominal risk-free rates over the maturity of the contract. Akram, Rime and Sarno (2008) study high frequency deviations from covered interest rate parity (CIP). They conclude that CIP holds at daily and lower frequencies. Hence, the log currency excess return approximately equals the interest rate differential less the rate of depreciation:

$$rx_{t+1} \approx i_t^* - i_t - \Delta s_{t+1}.$$

**Transaction Costs** Since we have bid-ask quotes for spot and forward contracts, we can compute the investor's actual realized excess return net of transaction costs. The *net* log currency excess

return for an investor who goes long in foreign currency is:

$$rx_{t+1}^l = f_t^b - s_{t+1}^a.$$

The investor buys the foreign currency or equivalently sells the dollar forward at the bid price ( $f^b$ ) in period  $t$ , and sells the foreign currency or equivalently buys dollars at the ask price ( $s_{t+1}^a$ ) in the spot market in period  $t + 1$ . Similarly, for an investor who is long in the dollar (and thus short the foreign currency), the net log currency excess return is given by:

$$rx_{t+1}^s = -f_t^a + s_{t+1}^b.$$

**Data** We start from daily spot and forward exchange rates in US dollars. We build end-of-month series from November 1983 to December 2009. These data are collected by Barclays and Reuters and available on Datastream. Lyons (2001) reports that bid-ask spreads from Reuters are roughly twice the size of inter-dealer spreads. We assume that net excess returns take place at these quotes. As a result, our estimates of the transaction costs are conservative. Lyons (2001) also notes that these indicative quotes track inter-dealer quotes closely, only lagging the inter-dealer market slightly at very high intra-day frequency. This is clearly not an issue here at monthly horizons. Our main data set contains at most 35 different currencies: Australia, Austria, Belgium, Canada, Hong Kong, Czech Republic, Denmark, Euro area, Finland, France, Germany, Greece, Hungary, India, Indonesia, Ireland, Italy, Japan, Kuwait, Malaysia, Mexico, Netherlands, New Zealand, Norway, Philippines, Poland, Portugal, Saudi Arabia, Singapore, South Africa, South Korea, Spain, Sweden, Switzerland, Taiwan, Thailand, United Kingdom. Some of these currencies have pegged their exchange rate partly or completely to the US dollar over the course of the sample. We keep them in our sample because forward contracts were easily accessible to investors. The euro series start in January 1999. We exclude the euro area countries after this data and only keep the euro series.

Based on large failures of covered interest rate parity, we chose to delete the following observa-

tions from our sample: South Africa from the end of July 1985 to the end of August 1985; Malaysia from the end of August 1998 to the end of June 2005; Indonesia from the end of December 2000 to the end of May 2007; Turkey from the end of October 2000 to the end of November 2001; United Arab Emirates from the end of June 2006 to the end of November 2006. In addition, there were widespread deviations from covered interest rate parity in the fall of 2008, as reported for example in Jones (2009). However, the implications for the magnitude of returns that we report are limited.<sup>6</sup>

As a robustness check, we also study a smaller data set that contains only 15 developed countries: Australia, Belgium, Canada, Denmark, Euro area, France, Germany, Italy, Japan, Netherlands, New Zealand, Norway, Sweden, Switzerland and United Kingdom. We first focus our description of our results on our large sample but we present all of our results on both samples.

**Portfolios** At the end of each period  $t$ , we allocate all currencies in the sample to six portfolios on the basis of their forward discounts  $f - s$  observed at the end of period  $t$ . Portfolios are rebalanced at the end of every month. They are ranked from low to high interest rates; portfolio 1 contains the currencies with the lowest interest rate or smallest forward discounts, and portfolio 6 contains the currencies with the highest interest rates or largest forward discounts. We compute the log currency excess return  $rx_{t+1}^j$  for portfolio  $j$  by taking the average of the log currency excess returns in each portfolio  $j$ . For the purpose of computing returns net of bid-ask spreads we assume that investors *short* all the foreign currencies in the *first* portfolio and go *long* in all the other foreign currencies.

The total number of currencies in our portfolios varies over time. We have a total of 9 countries at the beginning of the sample in 1983 and 26 at the end in 2009. We only include currencies for which we have forward and spot rates in the current and subsequent period. The maximum number of currencies attained during the sample is 34; the launch of the euro accounts for the subsequent decrease in the sample size.

## 1.2 Returns to Currency Speculation for a US investor

Table I provides an overview of the properties of the six currency portfolios from the perspective of a US investor. For each portfolio  $j$ , we report average changes in the spot rate  $\Delta s^j$ , the forward discounts  $f^j - s^j$ , the log currency excess returns  $rx^j = -\Delta s^j + f^j - s^j$ , and the log currency excess returns net of bid-ask spreads  $rx_{net}^j$ . We report log returns because these are the sum of the forward discount and the change in spot rates. We also report log currency excess returns on carry trades or high-minus-low investment strategies that go long in portfolio  $j = 2, 3, \dots, 6$ , and short in the first portfolio:  $rx_{net}^j - rx_{net}^1$ . All exchange rates and returns are reported in US dollars and the moments of returns are annualized: we multiply the mean of the monthly data by 12 and the standard deviation by  $\sqrt{12}$ . The Sharpe ratio is the ratio of the annualized mean to the annualized standard deviation.

The first panel reports the average rate of depreciation for all currencies in portfolio  $j$ . According to the standard uncovered interest rate parity (UIP) condition, the average rate of depreciation  $E_T(\Delta s^j)$  of currencies in portfolio  $j$  should equal the average forward discount on these currencies  $E_T(f^j - s^j)$ , reported in the second panel. Instead, currencies in the first portfolio trade at an average forward discount of -297 basis points, but they appreciate on average only by almost 64 basis points over this sample. This adds up to a log currency excess return of minus 233 basis points on average, which is reported in the third panel. Currencies in the last portfolio trade at an average discount of 901 basis points but they depreciate only by 282 basis points on average. This adds up to a log currency excess return of 620 basis points on average.

The fourth panel reports average log currency excess returns net of transaction costs. Since we rebalance portfolios monthly, and transaction costs are incurred each month, these estimates of net returns to currency speculation are conservative. After taking into account bid-ask spreads, the average return on the first portfolio drops to minus 117 basis points. Note that the first column reports *minus* the actual log excess return for the first portfolio, because the investor is short in these currencies. The corresponding Sharpe ratio on this first portfolio is minus 0.14. The return on the sixth portfolio drops to 338 basis points. The corresponding Sharpe ratio on the last

portfolio is 0.35.

The fifth panel reports returns on zero-cost strategies that go long in the high interest rate portfolios and short in the low interest rate portfolio. The spread between the net returns on the first and the last portfolio is 454 basis points. This high-minus-low strategy delivers a Sharpe ratio of 0.50, after taking into account bid-ask spreads. We also report standard errors on these average returns between brackets. The average returns on the last four investment strategies are statistically significantly different from zero.

Currencies in portfolios with higher forward discounts tend to experience higher real interest rates. The ex post real interest rate differences are computed off the forward discounts.<sup>7</sup> There is a large spread of 559 basis points in (ex post) real interest rates between the first and the last portfolio. The spread is somewhat smaller (412 basis points) on the sample of developed currencies.

Finally, the last panel reports the frequency of currency portfolio switches. We define the average frequency as the time-average of the following ratio: the number of portfolio switches divided by the total number of currencies at each date. The average frequency is 29.84 percent, implying that currencies switch portfolios roughly every three months. When we break it down by portfolio, we get the following frequency of portfolio switches (in percentage points): 20% for the 1st, 34% for the 2nd, 41% for the 3rd, 44% for the 4th, 42% for the 5th, and 14% for the 6th. Overall, there is substantial variation in the composition of these portfolios, but there is more persistence in the composition of the corner portfolios.

We have documented that a US investor with access to forward currency markets can generate large returns with annualized Sharpe ratios that are comparable to those in the US stock market. Table I also reports results obtained on a smaller sample of developed countries. We obtain similar results. The Sharpe ratio on a long-short strategy is 0.32.

### 1.3 Average vs. Current Interest Rate Differences

What fraction of the return differences across currency portfolios are due to differences in average interest rates vs. differences in current interest rates between currencies? In other words, are

we compensated for investing in high interest rate currencies or for investing in currencies with currently high interest rates? We address this question by sorting currencies on average forward discounts in the first half of the sample, and then computing the realized excess returns in the second part of the sample. Thus computed, these are returns on an implementable investment strategy.

The top panel in Table II reports the results from this sort on average forward discounts. The bottom panel report the results from the standard sort on current forward discounts over the same sample. Even the sort on average interest differences produces a monotonic pattern in excess returns: currencies with higher average interest rates tend to earn higher average returns. Before transactions costs, this sort produces a 5.34% ‘unconditional’ carry trade premium compared to a 10.16% conditional carry trade premium. Hence, the unconditional premium accounts for 52% of the total carry trade premium. After transaction costs, the numbers change to 2.83% and 6.28% respectively. After transaction costs, the conditional premium accounts for 45% of the total. However, the strategy with re-balancing by sorting on current interest rates delivers much higher Sharpe ratios than the unconditional strategy. The unconditional sort produces a Sharpe ratio of 0.23, compared to 0.70 for the conditional sort. Per unit of risk, the compensation for ‘conditional’ carry trade risk is much higher.

These unconditional sorts of currencies mainly seem to pick up variation in average real interest rates across currencies: the countries in the first portfolio have average real interest rate differentials of -96 basis points in the second half of the sample, compared to 243 basis points in the last portfolio.

## 2 Common Factors in Currency Returns

This section show that the sizeable currency excess returns described in the previous section are matched by covariances with risk factors.

## 2.1 Methodology

Linear factor models predict that average returns on a cross-section of assets can be attributed to risk premia associated with their exposure to a small number of risk factors. In the arbitrage pricing theory (APT) of Ross (1976), these factors capture common variation in individual asset returns. A principal component analysis on our currency portfolios reveals that two factors explain more than 80 percent of the variation in returns on these six portfolios. The top panel in Table III reports the loadings of our currency portfolios on each of the principal components as well as the fraction of the total variance of portfolio returns attributed to each principal component. The first principal component explains 70 percent of common variation in portfolio returns, and can be interpreted as a *level* factor, since all portfolios load equally on it. The second principal component, which is responsible for close to 12 percent of common variation, can be interpreted as a *slope* factor, since portfolio loadings increase monotonically across portfolios. Since average excess returns increase monotonically across portfolios, the second principal component is the only plausible candidate risk factor that might explain the cross-section of portfolio excess returns, as none of the other principal component exhibit monotonic variation in loadings.

Motivated by the principal component analysis, we construct two candidate risk factors: the average currency excess return, denoted  $RX$ , and the difference between the return on the last portfolio and the one on the first portfolio, denoted  $HML_{FX}$ . The correlation of the first principal component with  $RX$  is 0.99. The correlation of the second principal component with  $HML_{FX}$  is 0.94. Both factors are computed from net returns, after taking into account bid-ask spreads. The bottom panel confirms that we obtain similar results even when we exclude developing countries from the sample. It is important to point out that these components capture common variation in exchange rates, not interest rates. When we redo our principal component analysis on the changes in spot exchange rates that correspond to the currency portfolios, we get essentially the same results.

The two currency factors have a natural interpretation.  $HML_{FX}$  is the return in dollars on a zero-cost strategy that goes long in the highest interest rate currencies and short in the lowest

interest rate currencies.  $RX$  is the average portfolio return of a US investor who buys all foreign currencies available in the forward market. This second factor is essentially the currency “market” return in dollars available to an US investor, which is driven by the fluctuations of the US dollar against a broad basket of currencies.

**Cross-Sectional Asset Pricing** We use  $Rx_{t+1}^j$  to denote the average excess return in levels on portfolio  $j$  in period  $t + 1$ . All asset pricing tests are run on excess returns in levels, not log excess returns, to avoid having to assume joint log-normality of returns and the pricing kernel. In the absence of arbitrage opportunities, this excess return has a zero price and satisfies the following Euler equation:

$$E_t[M_{t+1}Rx_{t+1}^j] = 0.$$

We assume that the stochastic discount factor  $M$  is linear in the pricing factors  $\Phi$ :

$$M_{t+1} = 1 - b(\Phi_{t+1} - \mu_\Phi),$$

where  $b$  is the vector of factor loadings and  $\mu_\Phi$  denotes the factor means. This linear factor model implies a beta pricing model: the expected excess return is equal to the factor price  $\lambda$  times the beta of each portfolio  $\beta^j$ :

$$E[Rx^j] = \lambda' \beta^j,$$

where  $\lambda = \Sigma_{\Phi\Phi} b$ ,  $\Sigma_{\Phi\Phi} = E(\Phi_t - \mu_\Phi)(\Phi_t - \mu_\Phi)'$  is the variance-covariance matrix of the factor, and  $\beta^j$  denotes the regression coefficients of the return  $Rx^j$  on the factors. To estimate the factor prices  $\lambda$  and the portfolio betas  $\beta$ , we use two different procedures: a Generalized Method of Moments estimation (GMM) applied to linear factor models, following Hansen (1982), and a two-stage OLS estimation following Fama and MacBeth (1973), henceforth FMB. In the first step, we run a time series regression of returns on the factors. In the second step, we run a cross-sectional regression of average returns on the betas. We do not include a constant in the second step ( $\lambda_0 = 0$ ).

## 2.2 Results

Table IV reports the asset pricing results obtained using GMM and FMB on currency portfolios sorted by forward discounts. The left hand side of the table corresponds to our large sample of developed and emerging countries, while the right hand side focuses on developed countries. We describe first the results obtained on our large sample.

**Cross-sectional regressions** The top panel of the table reports estimates of the market prices of risk  $\lambda$  and the stochastic discount factor (henceforth SDF) loadings  $b$ , the adjusted  $R^2$ , the square-root of mean-squared errors  $RMSE$  and the  $p$ -values of  $\chi^2$  tests (in percentage points).<sup>8</sup> The market price of  $HML_{FX}$  risk is 550 basis points *per annum*. This means that an asset with a beta of one earns a risk premium of 5.50 percent per annum. Since the factors are returns, no arbitrage implies that the risk prices of these factors should equal their average excess returns. This condition stems from the fact that the Euler equation applies to the risk factor itself, which clearly has a regression coefficient  $\beta$  of one on itself. In our estimation, this no-arbitrage condition is satisfied. The average excess return on the high-minus-low strategy (last row of the top panel in Table IV) is 508 basis points. This value differs slightly from the previously reported mean excess return because we use excess returns in *levels* in the asset pricing exercise, but Table I reports *log* excess returns defined as differences between the forward discount and the changes in the log of the exchange rates. So the estimated risk price is only 42 basis points removed from the point estimate implied by linear factor pricing. The GMM standard error of the risk price is 225 basis points. The FMB standard error is 179 basis points. In both cases, the risk price is more than two standard errors from zero, and thus highly statistically significant.

The second risk factor  $RX$ , the average currency excess return, has an estimated risk price of 134 basis points, compared to a sample mean for the factor of 133 basis points. This is not surprising, because all the portfolios have a beta close to one with respect to this second factor. As a result, the second factor explains none of the cross-sectional variation in portfolio returns, and the standard errors on the risk price estimates are large: for example, the GMM standard error is 185 basis points. When we drop the dollar factor, the RMSE rises from 96 to 148 basis points, but

the adjusted  $R^2$  is still above 70 %. The dollar factor does not explain any of the cross-sectional variation in expected returns, but it is important for the level of average returns. When we include a constant in the 2nd step of the FMB procedure, the RMSE drops to 97 basis points with only  $HML_{FX}$  as the pricing factor. Adding a constant to the dollar risk factor is redundant because the dollar factor acts like a constant in the cross-sectional regression (all of the portfolios' loadings on this factor are equal to one).

The  $\lambda$ 's indicate whether risk is priced, and  $HML_{FX}$  risk clearly is in the data. The loadings (b) have a natural interpretation as the regression coefficients in a multiple regression of the SDF on the factors. The t-stats on  $b_{HML}$  consistently show that the carry trade risk factor helps to explain the cross-section of currency returns in a statistically significant way, while the dollar risk factor does not.

Overall, the pricing errors are small. The RMSE is 96 basis points and the adjusted  $R^2$  is 70 percent. The null that the pricing errors are zero cannot be rejected, regardless of the estimation procedure: all of the p-values (reported in percentage points in the column labeled  $\chi^2$ ) exceed 5%. These results are robust. They also hold in a smaller sample of developed countries, as shown in the right-hand side of Table IV.

**Time Series Regressions** The bottom panel of Table IV reports the constants (denoted  $\alpha^j$ ) and the slope coefficients (denoted  $\beta^j$ ) obtained by running time-series regressions of each portfolio's currency excess returns  $Rx^j$  on a constant and risk factors. The returns and  $\alpha$ 's are in percentage points per annum. The first column reports  $\alpha$ 's estimates. The second portfolio has a large negative  $\alpha$  of -155 basis points per annum, significant at the 5 percent level. The fourth portfolio has a large  $\alpha$  of 151 basis points per annum, significant at the 5 percent level. The other  $\alpha$  estimates are much smaller and not significantly different from zero. The null that the  $\alpha$ 's are jointly zero cannot be rejected at the 5 or 10 % significance level. Using a linear combination of the portfolio returns as factors entails linear restrictions on the  $\alpha$ s. When the two factors  $HML_{FX}$  and  $RX_{FX}$  are orthogonal, it is easy to check that  $\alpha^1 = \alpha^6$ , because  $\beta_{HML_{FX}}^6 - \beta_{HML_{FX}}^1 = 1$  by construction and  $\beta_{RX}^6 = \beta_{RX}^1 = 1$ . In this case, the risk prices exactly equal the factor means. This is roughly

what we find in the data.

The second column of the same panel reports the estimated  $\beta$ s for the  $HML_{FX}$  factor. These  $\beta$ s increase monotonically from -.39 for the first portfolio to .61 for the last currency portfolio, and they are estimated very precisely. The first three portfolios have betas that are negative and significantly different from zero. The last two have betas that are positive. The third column shows that betas for the dollar factor are essentially all equal to one. Obviously, this dollar factor does not explain any of the variation in average excess returns across portfolios, but it helps to explain the average level of excess returns. These results are robust and comparable to the ones obtained on a sample of developed countries (reported on the right hand side of the table).

A natural question is whether the unconditional betas of the bottom panel of Table IV are driven by the covariance between exchange rate changes and risk factors, or between interest rate changes and risk factors. This is important because the conditional covariance between the log currency returns and the carry trade risk factor obviously only depends on the spot exchange rate changes:

$$cov_t [rx_{t+1}^j, HML_{FX,t+1}] = -cov_t [\Delta s_{t+1}^j, HML_{FX,t+1}].$$

The regression of the log changes in spot rates for each portfolio on the factors reveals that these betas are almost identical to the ones for portfolio returns (with a minus sign), as expected.<sup>9</sup> Low interest currencies offer a hedge against carry trade risk because they appreciate when the carry return is low, not because the interest rates on these currencies increase. High interest rate currencies expose investors to more carry risk, because they depreciate when the carry return is low, not because the interest rates on these currencies decline. This is exactly the pattern that our no-arbitrage model in section 4 delivers. Our analysis within the context of the model focuses on conditional betas.<sup>10</sup>

**Average vs. Current Interest Rate Differences** In Table II we showed that the sorts on mean forward discounts produce a spread in currency returns of about half of the total spread. These portfolios still load very differently on  $HML_{FX}$ , the factor that we construct from the sort

on current interest rates. On the second part of the sample, starting in January 1995, the first portfolio's  $HML_{FX}$  loading is -0.49 (with a standard error of 0.07), and the loading of the sixth portfolio is 0.39 (0.07). Hence, the spread in loadings is 0.88, only 12 basis points less than the spread in the betas of the portfolios sorted by current interest rates. The market price of risk at 3.3%, however, is lower than the mean of  $HML_{FX}$  (6.9%) and is not precisely estimated over this short sample.

### 3 Robustness

This section provides more evidence on the nature of currency risk premia that directly supports a risk-based explanation of our findings.

#### 3.1 Other Test Assets: Beta-Sorted Portfolios

First, in order to show that the sorting of currencies on forward discounts really measures the currency's exposure to the risk factor, we build portfolios based on each currency's exposure to aggregate currency risk as measured by  $HML_{FX}$ . For each date  $t$ , we first regress each currency  $i$  log excess return  $rx^i$  on a constant and  $HML_{FX}$  using a 36-month rolling window that ends in period  $t - 1$ . This gives us currency  $i$ 's exposure to  $HML_{FX}$ , and we denote it  $\beta_t^{i,HML}$ . Note that it only uses information available at date  $t$ . We then sort currencies into six groups at time  $t$  based on these slope coefficients  $\beta_t^{i,HML}$ . Portfolio 1 contains currencies with the lowest  $\beta$ s. Portfolio 6 contains currencies with the highest  $\beta$ s. Table V reports summary statistics on these portfolios. The first panel reports average changes in exchange rates. The second panel shows that average forward discounts increase monotonically from portfolio 1 to portfolio 6. Thus, sorts based on forward discounts and sorts based on betas are clearly related, which implies that the forward discounts convey information about riskiness of individual currencies. The third panel reports the average log excess returns. They are monotonically increasing from the first to the last portfolio, even though the spread is smaller than the one created by ranking directly on interest rates. Clearly, currencies that co-vary more with our risk factor - and are thus riskier - provide

higher excess returns. The last panel reports the post-formation betas. They vary monotonically from  $-0.31$  to  $0.38$ . This finding is quite robust. When we estimate betas using a 12-month rolling window, we also obtain a 300 basis point spread between the first and the last portfolio.<sup>11</sup>

## 3.2 Other Factors: Splitting Samples

Second, to guard against a mechanical relation between the returns and the factors, we randomly split our large sample of developed and emerging countries into two sub-samples. To do so, we sorted countries alphabetically and consider two groups. We found that risk factors built using currencies that do not belong to the portfolios used as test assets can still explain currency excess returns.<sup>12</sup> However, the market price of risk appears higher and less precisely estimated than on the full sample, and thus further from its sample mean. This happens because, by splitting the sample, we introduce more measurement error in  $HML_{FX}$ . This shrinks the betas in absolute value (towards zero), lowers the spread in betas between high and low interest rate portfolios and hence inflates the risk price estimates. However, portfolio betas increase monotonically from the first to the last portfolio, showing that common risk factors are at work on currency markets.

## 3.3 Country-Level Asset Pricing

Third, we take our model to country-level data. We run country-level Fama and MacBeth (1973) tests. Creating portfolios of stocks could potentially lead to data-snooping biases (Lo and MacKinlay (1990)) and destroy information by shrinking the dispersion of betas (e.g. as argued recently by Ang, Liu and Schwarz (2010)). In order to address these concerns, we use country-level excess returns as test assets, but we continue to use the currency portfolios to extract our two currency risk factors  $HML_{FX}$  and  $RX$ . We first study unconditional currency excess returns before turning to conditional currency excess returns.

**Fama and MacBeth (1973)** The Fama and MacBeth (1973) procedure has two steps. In the first step, we run time series regressions of each country's  $i$  currency excess return on a constant,

$HML_{FX}$ , and  $RX$ :

$$Rx_{t+1}^i = c^i + \beta_{HML}^i HML_{FX,t+1} + \beta_{RX}^i RX_{t+1} + \epsilon_{i,t+1}, \text{ for a given } i, \forall t. \quad (3.1)$$

In a second step, we run cross-sectional regressions of all currency excess returns on betas:

$$Rx_t^i = \lambda_{HML,t} \beta_{HML}^i + \lambda_{RX,t} \beta_{RX}^i + \xi_t, \text{ for a given } t, \forall i.$$

We compute the market price of risk as the mean of all these slope coefficients:  $\lambda_c = \frac{1}{T} \sum_{t=1}^T \lambda_{c,t}$  for  $c = HML, RX$ . This procedure is identical to the original Fama and MacBeth (1973) experiment.

The excess returns on individual currencies that are used as test assets do *not* take into account bid-ask spreads because we do not know a priori if investors should take a short or long position on each particular currency. In the interest of consistency, we use the same risk factors  $HML_{FX}$  and  $RX$  reported in Table 1; those risk factors take into account bid-ask spreads. We obtain similar results with risk factors that do not take into account bid-ask spreads, but the means of the risk factor are higher.

**Unconditional country currency risk premia** Table VI reports our results on two samples. In both samples, the market prices of risk are positive and less than one standard error from the means of the risk factors. The square root of the mean squared errors and the mean absolute pricing error are larger than those obtained on currency portfolios, but we cannot reject the null hypothesis that all pricing errors are jointly zero. High beta countries tend to offer high unconditional currency excess returns.

**Conditional country currency risk premia** We now turn to conditional risk premia. We start by reporting the results obtained with managed investments and then turn to time-varying factor betas. Investors can adjust their position in a given currency based on the interest rate at the start of each period to exploit the return predictability and increase the Sharpe ratio. We consider such managed investment strategies to capture the cross-section of *conditional* expected excess returns

in addition to the raw currency excess returns. To construct these managed positions, we multiply each currency excess return with the appropriate beginning-of-month forward discount, normalized by subtracting the average forward discount across currencies and dividing by the cross-sectional standard deviation of forward discounts in the given period. We use the same procedure and the same risk factors as above on this augmented set of test assets; Table VI reports these results as well. The market prices of risk are positive and significant, and they are in line with those obtained on the unconditional returns. The cross-sectional fit has improved. The carry and dollar risk factors are priced in the cross-section of currency excess returns and account for a large share of the cross-sectional differences in country excess returns in both samples.

An alternative approach for testing asset pricing models with time-varying risk exposures is to estimate factor loadings using rolling windows instead of incorporating conditioning information explicitly. To estimate the risk prices, we run a set of cross-sectional regressions:

$$Rx_{t+1}^i = \lambda_{HML,t} \beta_{HML,t}^i + \lambda_{RX,t} \beta_{RX,t}^i + \xi_{t+1}, \text{ for a given } t, \forall i, \quad (3.2)$$

where  $\beta_{HML,t}^i$  and  $\beta_{RX,t}^i$  are estimated by running time-series regressions similar to equation (3.1) but over the sub-sample of  $T_{window}$  periods up to period  $t$ . We report results obtained with rolling windows of length  $T_{window} = 36$  months (therefore, we exclude currencies for which less than three years of observations are available - there are 6 such currencies in our sample). The model's cross-sectional fit is evaluated by comparing the true unconditional average returns with their predicted values:

$$E(Rx_{t+1}^i) = E(\lambda_{HML,t} \beta_{HML,t}^i + \lambda_{RX,t} \beta_{RX,t}^i), \forall i. \quad (3.3)$$

The results of tests based on this procedure are also reported in Table VI. The estimated prices of carry risk are very close (within half of a standard error) to the sample means of the  $HML_{FX}$  factor, at 4.6% in the full sample and 3.3% in the smaller sample of developed countries (compared to sample means of 5.1 and 3.1, respectively). The market price of carry risk is statistically significant in the full sample, but not in the smaller one. The estimated prices of dollar risk are similar to

those reported previously. The cross-sectional fit of the model is also similar to that with other methods, with high cross-sectional  $R^2$ s of 65.8% and 84.2% in the full and small sample.

Another standard approach for estimating dynamic factor loadings that allows us to use conditioning information without enlarging the asset space to include managed returns is to explicitly model betas as linear functions of the currency-specific forward discounts<sup>13</sup>. In particular, assume that  $\beta_{HML,t}^i = h_0^i + h_1^i z_t^i$  and  $\beta_{RX,t}^i = d_0^i + d_1^i z_t^i$ , where  $z_t^i$  is the country-specific forward discount, standardized as described above. The parameters  $h_0^i$ ,  $h_1^i$ ,  $d_0^i$  and  $d_1^i$  can be estimated from the linear regression

$$Rx_{t+1}^i = c^i + h_0^i HML_{FX,t+1} + h_1^i z_t^i HML_{FX,t+1} + d_0^i RX_{t+1} + d_1^i z_t^i RX_{t+1} + \epsilon_{i,t+1}, \text{ for a given } i. \quad (3.4)$$

The factor risk prices  $\lambda_{HML,t}$  and  $\lambda_{RX,t}$  can then be estimated by running the second-stage cross-sectional regressions (3.2) on the fitted conditional betas. The pricing errors and cross-sectional tests then can be used to evaluate the unconditional restriction (3.3) as before. The results of this estimation are in the bottom rows in Table VI. This method produces very similar results to the rolling-window approach, which provides further evidence for the role of forward discounts in capturing the currencies' dynamic exposures to common sources of risk.

The country-level results are consistent with our portfolio-level results. We focus on portfolios in the rest of the paper since they allow us to extract the slope factor. They also offer a simple nonparametric way of estimating conditional covariances, which are key for our analysis.

## 4 A No-Arbitrage Model of Exchange Rates

We derive new restrictions on the stochastic discount factors (at home and abroad) that need to be satisfied in order to reproduce the carry trade risk premium that we have documented in the data. These restrictions are different from the restrictions that need to be satisfied to reproduce the negative UIP slope coefficients. We impose minimal structure by considering a no-arbitrage model for interest rates and exchange rates. Our model has an exponentially-affine pricing kernel and

therefore shares some features with other models in this class, such as those proposed by Frachot (1996) and Brennan and Xia (2006), and, in particular, Backus et al. (2001). However, unlike these authors, we do not focus on currency pairs, but we consider a world with  $N$  different countries and currencies, where  $N$  is large. This allows us to distinguish between common and country-specific factors.<sup>14</sup>

In each country  $i$ , the logarithm of the SDF  $m^i$  follows

$$-m_{t+1}^i = \alpha^i + \chi^i z_t^i + \sqrt{\gamma^i z_t^i} u_{t+1}^i + \chi^i z_t^w + \sqrt{\delta^i z_t^w + \kappa^i z_t^i} u_{t+1}^w.$$

There is a common global state variable  $z_t^w$  and a country-specific state variable  $z_t^i$ . The common state variable enters the pricing kernel of all investors in  $N$  different countries. The country-specific state variable obviously does not. This distinction between idiosyncratic (country-specific) or common (global) risk is very natural in a setting with a large number of countries and currencies.

The currency-specific innovations  $u_{t+1}^i$  and global innovations  $u_{t+1}^w$  are *i.i.d* gaussian, with zero mean and unit variance;  $u_{t+1}^w$  is a world shock, common across countries, while  $u_{t+1}^i$  is country-specific (and thus uncorrelated across countries). The same innovations that drive the pricing kernel variation will govern the dynamics of the country-specific and world volatility processes. The country-specific volatility component is governed by an auto-regressive square root process:

$$z_{t+1}^i = (1 - \phi)\theta + \phi z_t^i + \sigma \sqrt{z_t^i} u_{t+1}^i.$$

The world volatility component is also governed by a square root process:

$$z_{t+1}^w = (1 - \phi)\theta + \phi z_t^w + \sigma \sqrt{z_t^w} u_{t+1}^w.$$

We assume that the standard deviation of innovations to the common and country-specific factors is identical; we refer to this volatility as  $\sigma$ . We also assume that the price of local risk only depends on local risk aversion, but the price of global risk is allowed to depend on both local and global risk aversion. As a result, the conditional market price of risk has a domestic component given by

$\sqrt{\gamma^i z_t^i}$  and a global component given by  $\sqrt{\delta^i z_t^w + \kappa^i z_t^i}$ .

We assume that financial markets are complete, but that some frictions in the goods markets prevent perfect risk-sharing across countries. As a result, the change in the real exchange rate  $\Delta q^i$  between the home country and country  $i$  is:

$$\Delta q_{t+1}^i = m_{t+1} - m_{t+1}^i,$$

where  $q^i$  is measured in country  $i$  goods per home country good. An increase in  $q^i$  means a real appreciation of the home currency. For the home country (the US), we drop the superscript.

**Assumption 1.** *All countries share the same parameters  $(\alpha, \chi, \gamma, \kappa)$ , but not  $\delta$ . The home country has the average  $\delta$  loading on the global component.*

Hence, we can drop the superscript  $i$  for all parameters except  $\delta^i$ . All of the parameters are assumed to be nonnegative. With this notation the real risk-free interest rate (in logarithms) is given by

$$r_t^i = \alpha + \left( \chi - \frac{1}{2}(\gamma + \kappa) \right) z_t^i + \left( \chi - \frac{1}{2}\delta^i \right) z_t^w.$$

The standard object of interest is the slope coefficient from a UIP regression of exchange rate changes on the interest rate differential. For an ‘average’ country with the same exposure to global innovations as the US ( $\delta^i = \delta$ ) this is given by  $Cov(\Delta q_{t+1}^i, r_{t+1}^i - r_{t+1}) / Var(r_{t+1}^i - r_{t+1}) = \chi / (\chi - \frac{1}{2}(\gamma + \kappa))$ .<sup>15</sup> Large values of  $\gamma$  and  $\kappa$  deliver negative UIP slope coefficients.

Our focus is on the *cross-sectional* variation in conditional expected excess returns. Since the log pricing kernel  $m_{t+1}$  and the log excess returns  $rx_{t+1} = r_{t+1}^i - r_{t+1} - \Delta q_{t+1}^i$  are jointly normally distributed, the Euler equation  $E[MR^i] = 1$  implies that the expected excess return in levels (i.e. corrected for the Jensen term) is the conditional covariance between the log pricing kernel and returns:

$$E_t[rx_{t+1}^i] + \frac{1}{2}Var_t[rx_{t+1}^i] = -Cov_t[m_{t+1}, rx_{t+1}^i] = Var_t[m_{t+1}] - Cov_t[m_{t+1}^i, m_{t+1}], \quad (4.1)$$

where lower letters denote logs. The second equality follows because only the exchange rate component  $\Delta q_{t+1}^i = m_{t+1} - m_{t+1}^i$  of the log currency returns  $rx_{t+1}^i$  matters for the conditional covariance.

## 4.1 Restricted Model

In order to explore the role of heterogeneity in the global risk exposures across currencies captured by  $\delta^i$  on the cross-section of expected currency returns, we first focus on a restricted version of the model in which the time-variation in the global component of the conditional price of risk only depends on the global factor:  $\kappa = 0$ . In this restricted version, the logarithm of the SDF  $m^i$  reduces to a more familiar two-factor Cox, Ingersoll and Ross (1985)-type process such as the one exploited by Backus et al. (2001), with the key difference being the heterogeneity in  $\delta^i$ .

Using the expression for the pricing kernels, equation (4.1) simplifies to:

$$E_t[rx_{t+1}^i] + \frac{1}{2}Var_t[rx_{t+1}^i] = \gamma z_t + \sqrt{\delta z_t^w} \left( \sqrt{\delta z_t^w} - \sqrt{\delta^i z_t^w} \right).$$

We can express this risk premium in terms of quantities and prices of risk. The loading on the domestic (dollar) shock is equal to 1 for returns on any currency, and  $\gamma z_t$  is the price of dollar-specific risk. The risk price for global shocks demanded by the domestic investor is  $\delta z_t^w$  and the quantity of global risk in currency  $i$  depends on the relative exposures of the two SDFs to the global shock; since higher  $\delta^i$  implies lower interest rates, *ceteris paribus*, this loading can be interpreted as carry beta:

$$\beta_t^{Carry} = \frac{\sqrt{\delta z_t^w} - \sqrt{\delta^i z_t^w}}{\sqrt{\delta z_t^w}} = 1 - \sqrt{\frac{\delta^i}{\delta}}. \quad (4.2)$$

The currency risk premium is *independent* of the foreign country-specific factor  $z_t^i$ . That is why we need asymmetric loadings on the common component as a source of variation in currency risk premia across currencies. The currency risk premium is also independent of the foreign country-specific loading  $\gamma^i$ . We have thus set  $\gamma^i$  equal to  $\gamma$  to keep the model parsimonious. In the absence of asymmetries in the exposure to global shocks, all currency risk premia are identical and equal to  $\gamma z_t$ , an implication that is clearly at odds with the data. Our sorts of currencies by current

interest rates have shown a large amount of cross-sectional variation in currency risk premia.

**Building Currency Portfolios to Extract Factors** We sort currencies into portfolios based on their forward discounts, as we have done in the data. We use  $H$  to denote the set of currencies in the last portfolio and  $L$  to denote the currencies in the first portfolio. The carry trade risk factor  $hml$  and the dollar risk factor  $\overline{rx}$  are defined as follows:

$$\begin{aligned} hml_{t+1} &= \frac{1}{N_H} \sum_{i \in H} rx_{t+1}^i - \frac{1}{N_L} \sum_{i \in L} rx_{t+1}^i, \\ \overline{rx}_{t+1} &= \frac{1}{N} \sum_i rx_{t+1}^i, \end{aligned}$$

where  $N_H$  and  $N_L$  denote the number of currencies in each portfolio. We let  $\overline{\sqrt{x_t}}$  denote the average of  $\sqrt{x_t^j}$  across all currencies in portfolio  $j$ . The portfolio composition changes over time, and in particular, it depends on the global state variable  $z_t^w$ .

In this setting, the carry trade and dollar risk factors have a very natural interpretation. The first one measures the common innovation, while the second one measures the domestic country-specific innovation. In order to show this result, we appeal to the law of large numbers, and we assume that the country-specific shocks average out within each portfolio.

**Proposition 4.1.** *The innovation to the  $hml$  risk factor only measures exposure to the common factor  $u_{t+1}^w$ , and the innovation to the dollar risk factor only measures exposure to the country-specific factor  $u_{t+1}$ :*

$$\begin{aligned} hml_{t+1} - E_t[hml_{t+1}] &= \left( \sqrt{\delta_t^L} - \sqrt{\delta_t^H} \right) \sqrt{z_t^w} u_{t+1}^w, \\ \overline{rx}_{t+1} - E_t[\overline{rx}_{t+1}] &= \sqrt{\gamma} \sqrt{z_t} u_{t+1}. \end{aligned}$$

**The Role of Heterogeneity** When currencies share the same loading on the common component, there is no *hml* risk factor. However, if lower interest rate currencies have different exposure to the common volatility factor –  $\sqrt{\delta^L} \neq \sqrt{\delta^H}$  – then the innovation to *hml* measures the common innovation to the SDF. As a result, the return on the zero-cost strategy *hml* measures the stochastic discount factors' relative exposure to the common shock  $u_{t+1}^w$ .

**Proposition 4.2.** *The hml betas and the  $\overline{rx}$  betas of the returns on currency portfolio  $j$  are:*

$$\begin{aligned}\beta_{hml,t}^j &= \frac{\sqrt{\delta} - \sqrt{\delta_t^j}}{\sqrt{\delta^L} - \sqrt{\delta^H}}, \\ \beta_{rx,t}^j &= 1.\end{aligned}$$

The betas for the dollar factor are all one. Not so for the carry trade risk factor. If the sorting of currencies on interest rate produces a monotonically decreasing ranking of  $\delta$  on average, then the *hml* betas will increase monotonically as we go from low to high interest rate portfolios. As it turns out, the model with asymmetric loadings automatically delivers this if interest rates decrease when global risk increases. This case is summarized in the following condition:

**Condition 4.1.** *The precautionary effect of global volatility on the real short rate dominates if:*

$$0 < \chi < \frac{1}{2}\delta^i.$$

This condition is intuitive and has a natural counterpart in most consumption-based asset pricing models: when precautionary saving demand is strong enough, an increase in the volatility of consumption growth (and, consequently, of marginal utility growth) lowers interest rates.

There is empirical evidence to support this assumption. The de-trended short-term interest rate predicts U.S. stock returns with a negative sign (see Fama and French (1989) for the original evidence and Lettau and Ludvigson (2001) for a recent survey of the evidence), consistent with higher Sharpe ratios in low interest rate countries. To check this, we sort the same set of countries

into six portfolios by their forward discounts, and we compute local currency equity returns in each portfolio. The Sharpe ratio is 0.5 in the lowest interest rate portfolio vs 0.1 in the highest interest rate portfolio. Verdelhan (2010) reports similar findings on developed countries. Sorting by real interest rates deliver similar results: 0.51 in portfolio 1 compared to 0.11 in portfolio 6.

The real short rate depends both on country-specific factors and on a global factor. The only sources of cross-sectional variation in interest rates are the shocks to the country-specific factor  $z_t^i$ , and the heterogeneity in the SDF loadings  $\delta^i$  on the world factor  $z^w$ . As a result, as  $z^w$  increases, on average, the currencies with the high loadings  $\delta$  will tend to end up in the lowest interest rate portfolios, and the gap  $\left(\sqrt{\delta_t^L} - \sqrt{\delta_t^H}\right)$  increases. This implies that in bad times the spread in the loadings increases. Hence, the restricted model can generate variation in currency portfolio betas, even though the individual currencies' carry betas in (4.2) are constant.

## 4.2 Full Model

The restricted version of the model analyzed above implies that currencies with high  $\delta$  loadings will have low interest rates on average, and earn low average excess returns, while the opposite holds for currencies with low  $\delta$ . As we show in section 1.3, such permanent heterogeneity across currencies explains at most half of the cross-sectional variation in expected currency returns. The full model imputes variation in excess returns to dynamic evolution in individual currency betas, as well as to the permanent differences in these betas.

The expected excess return in levels (i.e. corrected for the Jensen term) in the full model is given by

$$E_t[rx_{t+1}^i] + \frac{1}{2}Var_t[rx_{t+1}^i] = \gamma z_t + (\delta z_t^w + \kappa z_t) - \sqrt{\delta z_t^w + \kappa z_t} \sqrt{\delta^i z_t^w + \kappa z_t^i}.$$

Relative to the restricted model, the foreign part of the currency risk premium  $Cov_t[m_{t+1}^i, m_{t+1}]$  now has an additional country-specific component that depends on  $z_t^i/z_t$ . This new component captures transitory variation in the exposure of currencies to the global innovation, in addition to the permanent differences in exposure to the common innovation governed by  $\delta^i$ . As foreign

volatility increases  $z_t^i$ , the foreign SDF becomes more exposed to global innovations, and, as a result, its currency beta w.r.t the global shock decreases. The full model generates variation in individual currency betas in addition to currency portfolio betas. Again, cross-sectional variation in  $\gamma^i$  (exposure to country-specific shocks) does not help to generate cross-sectional variation in currency risk premia.

As before, two portfolios allow us to recover the innovations to the domestic pricing kernel:

$$\begin{aligned} hml_{t+1} - E_t[hml_{t+1}] &= \left( \frac{1}{N_L} \sum_{i \in L} \sqrt{\delta^i z_t^w + \kappa z_t^i} - \frac{1}{N_H} \sum_{i \in H} \sqrt{\delta^i z_t^w + \kappa z_t^i} \right) u_{t+1}^w, \\ \overline{rx}_{t+1} - E_t[\overline{rx}_{t+1}] &= \sqrt{\gamma z_t^w} u_{t+1} + \left( \sqrt{\delta z_t^w + \kappa z_t} - \frac{1}{N} \sum_i \sqrt{\delta^i z_t^w + \kappa z_t^i} \right) u_{t+1}^w. \end{aligned}$$

The *hml* portfolio will have positive average returns if the pricing kernels of low interest rate currencies are more exposed to the global innovation:

$$\frac{1}{N_L} \sum_{i \in L} \sqrt{\delta^i z_t^w + \kappa z_t^i} > \frac{1}{N_H} \sum_{i \in H} \sqrt{\delta^i z_t^w + \kappa z_t^i}$$

This will happen in equilibrium if the following conditions are satisfied:

**Condition 4.2.** *The precautionary effect of domestic and global volatility on the real short rate dominates if:*

$$0 < \chi < \frac{1}{2} \delta^i, \quad 0 < \chi < \frac{1}{2} (\gamma + \kappa).$$

If these conditions are satisfied, then an increase in domestic volatility lowers the real risk-free rate and temporarily implies higher exposure of the pricing kernel to the global innovation and hence lower betas for that particular currency. Hence, the unrestricted model contributes a second mechanism through which lower interest currencies earn lower risk premia than higher interest rate currencies: variation in individual currency betas that is tied to interest rates in that currency.

### 4.3 Inflation

Finally, we specify a process for the nominal pricing kernel, in order to match moments of nominal interest rates and exchange rates. The log of the nominal pricing kernel in country  $i$  is simply given by the real pricing kernel less the rate of inflation  $\pi^i$ :

$$m_{t+1}^{i,\$} = m_{t+1}^i - \pi_{t+1}^i.$$

Inflation is composed of a country-specific component and a global component. We simply assume that the same factors driving the real pricing kernel also drive expected inflation. In addition, inflation innovations in our model are not priced. Thus, country  $i$ 's inflation process is given by

$$\pi_{t+1}^i = \pi_0 + \eta^w z_t^w + \sigma_\pi \epsilon_{t+1}^i,$$

where the inflation innovations  $\epsilon_{t+1}^i$  are i.i.d. gaussian. It follows that the nominal risk-free interest rate (in logarithms) is given by

$$r_t^i = \pi_0 + \alpha + \left( \chi - \frac{1}{2}(\gamma + \kappa) \right) z_t^i + \left( \chi + \eta^w - \frac{1}{2}\delta^i \right) z_t^w - \frac{1}{2}\sigma_\pi^2,$$

Importantly, the currency risk premia on the one-period contracts that we consider in the data do not depend on the correlation between the innovations to the pricing kernel and the volatility processes, which we set to minus one, following the convention in the term structure literature. This correlation governs the slope of the term structure. For example, if we set this correlation to zero, eliminating conditional bond risk premia altogether, we still get the exact same expressions for the one-period currency risk premia in equation (4.3). Of course, the theoretical currency risk premia on contracts with longer maturity do depend on this correlation. Yet, empirically, Bekaert, Wei and Xing (2007) find that term premia only play a minor role in explaining currency risk premia.

We now turn to the calibration of this no-arbitrage model. We show that it can match the

key moments of currency returns in the data, while also matching the usual moments of nominal interest rates, exchange rates and inflation.

## 4.4 Calibration

We calibrate the model by targeting annualized moments of monthly data. A version of our model that is calibrated to match the key moments of interest rates and exchange rates can match the properties of carry trade returns.

### 4.4.1 Moments

The calibration proceeds in two steps. In the first step, we calibrate a symmetric version of the model: all countries have the same parameters, including  $\delta$ . All of the target moments of interest rates, exchange rates and inflation have closed-form expressions in this symmetric version of the model, assuming the moments of the square root processes exist. In the second stage we introduce enough heterogeneity in  $\delta$  to match the carry trade risk premium.

**Symmetric Model** Let us start with a symmetric version of the full model. We first focus on real moments. There are 8 parameters in the real part of the model: 5 parameters govern the dynamics of the real stochastic discount factors ( $\alpha$ ,  $\chi$ ,  $\gamma$ ,  $\kappa$ , and  $\delta$ ) and 3 parameters ( $\phi$ ,  $\theta$ , and  $\sigma$ ) describe the evolution of the country-specific and global factors ( $z$  and  $z^w$ ).

We choose these parameters to match the following 8 moments in the data: the mean, standard deviation and autocorrelation of the US real short-term interest rates, the standard deviation of changes in real exchanges rates, the cross-sectional mean of the real UIP slope coefficients, the cross-country correlation of real interest rates, the maximum Sharpe ratio ( the standard deviation of the log SDF) and a Feller parameter (equal to  $2(1 - \phi)\theta/\sigma^2$ ), which helps ensure that the  $z$  and  $z^w$  processes remain positive.<sup>16</sup> These 8 moments as well as the targets in the data that we match are listed in Panel A of Table VII.

The data for this calibration exercise come from Barclays and Reuters (Datastream). Because of data availability constraints, we focus on the subset of developed countries. The sample runs

from 11/1983 to 12/2009. However, for the US real interest rates data, we use the real zero-coupon yield curve data for the US provided by J. Huston McCulloch on his website; the sample covers 1/1997–10/2009. For other countries, we use the past 12-month changes in the log CPI index to proxy for expected inflation when computing real interest rates. Inflation itself is computed as the one-month change in the log CPI index. The average UIP slope coefficient in our sample is -0.53 on nominal series. However, the average real UIP slope coefficient is smaller (-0.9).

We target a UIP slope coefficient of  $-0.5$ , an average real interest rate of  $1.4\%$  per annum, an annualized standard deviation of the real interest rate of  $.5\%$  per annum, and an autocorrelation (in monthly data) of  $0.95$ . The annual standard deviation of real exchange rate changes is  $10.8\%$ . We target a maximum Sharpe ratio of  $0.5$ . This is the average Sharpe ratio on equity returns (in local currency) in our sample for the lowest interest rate currencies with the highest Sharpe ratios. The average pairwise correlation of real interest rates is  $.2$ . The annual dollar risk premium is  $0.5\%$  per annum. A Feller coefficient of  $20$  ensures that all of the state variables following square-root processes are positive (this is exact in the continuous-time approximation, and implies a negligible probability of crossing the zero bound in discrete time).

We obtain the 3 inflation parameters ( $\eta^w$ ,  $\sigma^\pi$ , and  $\pi_0$ ) by targeting the mean, standard deviation as well as the fraction of inflation that is explained by the common component. In Panel B of Table VII, we list the expression for the variance of inflation and the fraction explained by the common component. We target an annualized standard deviation for inflation of  $1.1\%$  and an average inflation rate of  $2.9\%$ .  $26\%$  of inflation is accounted by the common component. Finally, for completeness, Panel C also shows the implied moments of nominal interest rates and exchange rates in this symmetric version of the model. The implied correlation of nominal interest rates is too high. Introducing heterogeneity in  $\delta$  will address this problem.

Then, we solve a system of 11 equations to recover these 11 parameter values. The parameter values that we obtain are listed in Table VIII. Recall that in the symmetric version of the model all countries share the same  $\delta$ ; we chose a value of  $12.84$  to match the moments described above. In the next step, we introduce heterogeneity in the  $\delta$ s.

**Heterogeneity** In the second stage of the calibration, we introduce enough heterogeneity in the SDF loadings  $\delta$  on the global shock across countries to match an empirical carry trade risk premium of 5.88% for the subset of developed countries – this is the carry risk premium before bid-ask spreads; the model obviously does not have transaction costs. The home country keeps the  $\delta$  value of 12.84. Table VIII shows the range of  $\delta$ s for the other countries. The  $\delta^i$ s are linearly spaced on the interval  $[\underline{\delta}, \bar{\delta}]$  for all 30 currencies in our simulation. The moments reported were generated by drawing 100,000 observations from a model with 30 currencies.

Table IX presents the simulation results. We list the moments for the nominal and real interest rates, exchange rates and inflation in the data, as well as the moments implied by the model. Panel I reports the moments for the US, i.e., the home country in the model. The model's home country interest rates match the US interest rates in the data relatively well.

The average nominal interest rate is 4.7% in the model and 4.3% in the US data. The model slightly under-predicts the volatility of US nominal interest rates (0.6% vs 0.5%), because the only variation in expected inflation is the common factor  $z^w$ . Finally, the model under-predicts the persistence of nominal interest rates (0.98 in the data vs 0.92 in the model).

The model produces an average domestic real interest rate of 1.8% with a standard deviation of 0.4%, compared to 1.7% and 0.2% respectively in the US TIPS data and 1.4% and 0.5% using past annual inflation to proxy for expected inflation. The autocorrelation is 0.92, close to the data. These values are also close to the ones reported in Ang, Bekaert and Wei (2008). The model matches the mean and standard deviation of US inflation, but the model under-predicts the persistence of inflation: the first-order autocorrelation at monthly frequencies is 0.46 in the data compared to 0.27 in the model.

Panel II reports the moments for the cross-section of countries. The model delivers real interest rates that are as correlated to the US ones as their actual counterparts. The simulated real interest rates are on average lower, less volatile and more persistent than the ex post real interest rates in the data, but these are subject to caution. We do not have time-series of real interest rates for the countries in our sample (except for the US), and, as already noted, we use a proxy for expected

inflation.

The nominal interest rates produced by the model are somewhat lower and less volatile than those in the data. The model roughly matches the average pairwise correlation of foreign with US interest rates: 0.5 in the model and in the data. The correlation in interest rates is driven by the common factor  $z^w$ . The model matches the mean and persistence of the inflation rates but slightly underestimates their volatilities. The model also matches the fraction of inflation rates' variations that are explained by the common component in inflation (26% vs 31%). Recall that there is no inflation risk premium in the model. As a result, we could choose a richer process for (expected) common inflation that better matches the nominal interest rate and inflation data without changing any of our asset pricing results. However, to keep the model parsimonious, we chose not to, since inflation does not play a role in our mechanism.

Finally, we turn to exchange rates. In the model, the cross-sectional average of the standard deviation of changes in the log spot rates is 12.3%; the corresponding number in the data is 10.2%. Given that the standard deviation of the log pricing kernel is 53%, this implies that the pricing kernels have to be highly correlated across countries (see Brandt, Cochrane and Santa-Clara (2006)): the average pairwise correlation of the pricing kernels is 0.97. The cross-sectional average of the UIP slope coefficient is -.53 in the data, compared to -.46 in the model. However, the model substantially under-predicts the amount of cross-sectional variation in the UIP slope coefficient in the data because we have shut down all sources of heterogeneity except in the  $\delta$ s.

#### 4.4.2 Simulated Portfolios

Using the simulated data, we build currency portfolios in the same way as we did in the actual data. Table X reports the realized returns on these currency portfolios in the model. Panel I reports the results obtained when sorting on current forward discounts. These moments should be compared against the same moments in the data reported in Table I.

In the model, the volatility of changes in the exchange rates varies from 11.6% for portfolio 1 to 9.3% for portfolio 5. In the data, this volatility ranges from 9.5% to 10.3% on our small sample (7.4% to 9.7% in the large sample). As a result, the model over-predicts the volatility of changes

in spot rates portfolio by portfolio by at most 200 basis points.

In the model, the volatility of the forward discounts is around 105 basis points for all portfolios. As a result, the model overstates the volatility of interest rates in portfolios 1-5 in both samples and understates the volatility of interest rates in portfolio 6 in our large sample. The model also under-predicts the average interest rates in portfolio 6. In the data, portfolio 6 is comprised of countries which temporarily experience unusually high and volatile inflation. Our parsimonious specification of a single inflation process for all countries and currencies is not rich enough to match this. However, real, not nominal, interest rates matter for currency excess returns. The model does a much better job matching the moments of average real interest differences.

When sorting currencies by current interest rates, the model produces a carry trade risk premium of 5.91% per annum (4.54% in the data in our large sample). The annualized Sharpe ratio is 0.48 (.50 in the data).

Panel II reports the results obtained when sorting by the average forward discounts. The long-short excess return drops to 3.48%, about 60 % of the total carry trade risk premium. In the data, permanent differences in exposure to global innovations account for half of the total carry trade premium; in the model, they account for 60%.<sup>17</sup>

By sorting on average forward discounts, we really are sorting by real interest rates. In the model, there is a 158 basis point spread between real interest rates in the first and the last portfolio. In the data, we found a similar pattern (see Table I), but the variation in real interest rates that we documented was much bigger.

The model matches the turnover data reported in panel III rather well. For the currency portfolios in the mid range, the turnover is about 2.5 trades per portfolio (1.2 in the data). This translates into a turnover rate (turnover per portfolio per currency) of about 45%; the rate is similar to that in the data (40 to 45%), mainly because in the early part of the sample we had very few currencies in each portfolio.

The simulated market price of carry risk varies for two reasons. First, it is high when the world risk factor  $z^w$  is high. Second, this effect is amplified by changes in portfolio composition: higher

world risk price drives the selection of low-global risk countries into high interest rate portfolios, and vice versa. Thus, in “bad times,” when  $z^w$  is high, the spread between the average  $\delta$  in the first and the last portfolio increases.

Despite the low unconditional market beta of the carry trade in the data, the carry risk factor  $HML_{FX}$  is very highly correlated with the stock market during periods of increased market volatility. The recent sub-prime mortgage crisis offers a good example. Between July 2007 and March 2008, the correlation between US stock returns and  $HML_{FX}$  was .78. This pattern is consistent with the model. In the two-factor affine model, the conditional correlation of  $HML_{FX}$  and the SDF in the home country is:

$$\text{corr}_t(HML_{t+1}, m_{t+1}) = -\sqrt{\frac{\delta z_t^w + \kappa z_t}{\delta z_t^w + (\gamma + \kappa) z_t}}.$$

In the restricted model, this expression collapses to:

$$\text{corr}_t(HML_{t+1}, m_{t+1}) = -\sqrt{\frac{\delta z_t^w}{\delta z_t^w + \gamma z_t}}.$$

As the global component of the conditional market price of risk  $z_t^w$  increases, the conditional correlation between the stochastic discount factor at home and the carry trade returns  $HML_{FX}$  increases.

## 4.5 Testing the Model

Finally, we subject our model to some ‘out-of-sample tests’. We start by checking whether the model accurately describes the time-variation in currency betas.

### 4.5.1 Time-varying Betas

A statistically powerful way to capture time-variation in the individual currencies conditional betas with respect the two factors is to impose a functional relationship between betas and the conditioning variables (the forward discounts) that is the same across currencies. If this relationship

is linear, as assumed in equation (3.4), it can be estimated by running a pooled regression (e.g. as suggested by Cochrane (2011)) for the entire panel of currencies:

$$Rx_{t+1}^i = c^i + b_{HML} HML_{FX,t+1} + b_{z^i \times HML} z_t^i HML_{FX,t+1} + b_{RX} RX_{t+1} + b_{z^i \times RX} z_t^i RX_{t+1} + \epsilon_{i,t+1}, \quad (4.3)$$

where the fixed effects  $c^i$  represent country-specific pricing errors.

Table XI presents the results of this estimation (omitting the fixed effects), for the subsample of the developed countries and for the whole sample. The coefficient  $b_{HML}$  captures an average country's unconditional loading on the  $HML_{FX}$  factor; not surprisingly it is small (0.07) and not significantly different from zero. Also not surprisingly, the coefficient  $b_{RX}$  that measures the average loading on the dollar risk factor is equal to one for the entire sample, and is somewhat lower at 0.85 in the developed countries sample. The variation in the conditional  $HML_{FX}$  betas is measured by the coefficient  $b_{z \times HML}$ . It reaches a value of 0.3 (for the entire sample) and, jointly with the unconditional loading, implies that a currency whose forward discount is one cross-sectional standard deviation higher than the average at that time has a conditional beta of 0.37. This coefficient is highly statistically significant. This confirms that the forward discounts contain conditioning information that is important for understanding the dynamics of carry beta. Finally, the conditional variation in the dollar factor loading captured by  $b_{z \times RX}$  is essentially zero. The last panel reports the results obtained on model-generated data. The model does a remarkable job in replicating the time variation in the betas. In the model, the coefficient  $b_{HML}$  is equal to 0.08,  $b_{RX}$  is 1, and  $b_{z \times HML}$  is equal to 0.35.

Finally, we also replicate on simulated data the asset pricing tests obtained on individual currencies. To save space, results are reported in the separate appendix. The price of carry risk estimated using the cross-sectional Fama-MacBeth regressions using both unconditional and conditional betas is close to the sample mean of the factor, and the model is able to explain roughly 60 – 70% of sample variation in average currency returns.

### 4.5.2 Characteristics vs Covariances

Currency-specific attributes other than interest rates could explain some of our findings; maybe some currencies earn high returns merely because they have high interest rates, not because their returns co-vary positively with  $HML_{FX}$ . By sorting currencies on interest rate characteristics and using  $HML_{FX}$  as a factor, are we simply measuring the effects of interest rate characteristics on currency returns? We address this concern in two ways. First, we run tests to discriminate between these two explanations on actual and model-generated data. Second, we test other implications of the model.

The results in the top panel of Table XII suggest that we are simply picking up the effects of characteristics. This panel reports the cross-sectional asset pricing results obtained after adding the average interest rate difference for each currency portfolio, which we can call the characteristic, as a factor. The carry trade risk factor is no longer statistically significant. On the basis of this ‘horse race’ between the risk factor and the characteristic, one would conclude that the characteristic wins. However, in the bottom panel, we run the same estimation on simulated data from our calibrated no-arbitrage model in which only the risk is priced, not the characteristic. We use a small sample of 300 periods from the same simulation with 30 currencies that we used in section 4.4. The simulation-based estimates are essentially the same as the actual estimates from the data; the characteristic drives out the risk factor. The estimated risk price for  $HML_{FX}$  has the wrong sign.

This result is not surprising. In the model, as in the data, there is no variation in exposure to  $HML_{FX}$  across different currencies that is independent of interest rates. Furthermore, interest rates are computed from market prices that are recorded without measurement error; factor loadings are not. So, the outcome of this horse race, in which the risk factor is at a serious disadvantage, does not help to distinguish between these competing explanations.

### 4.5.3 Volatility as a Risk Factor

As a final test of our model we consider a measure of global financial market volatility as another proxy for the common risk factor. We expect global volatility to increase in bad times for global investors. If innovations to the common component of marginal utility growth  $u^w$  are indeed correlated with innovations to global volatility  $z^w$ , then volatility innovations could proxy for  $HML_{FX}$  innovations. In our model, these innovations are perfectly negatively correlated, so that volatility should command a negative price of risk.

In the data, our volatility measure is the average volatility of stock returns in local currency across all currencies in our sample. To build our volatility factor, we first compute the standard deviation over one month of daily MSCI changes for each currency, and then the cross-sectional mean of these volatility series. Our risk factor corresponds to volatility innovations, obtained as log differences of our global volatility series.

The top panel in Table XIII reports the loadings of different portfolio returns on the equity volatility factor. These loadings confirm our intuition: they decrease monotonically from the first to the last portfolio from 0.37 to -0.81 in the full sample (reported in the left panel), and from .58 to -.59 in the case of developed countries (reported in the right panel). High interest rate countries tend to offer low returns when equity volatility increases. Low interest rate countries, on the contrary, offer high returns when volatility goes up. As a result, the estimated price of volatility is negative (and statistically significant), as predicted by the model. Building on our work, Menkho, Sarno, Schmeling and Schrimpf (2010) find that a measure of global volatility obtained from currency markets also explains the cross-section of our currency portfolios. Those results are also consistent with our model.

While the equity volatility risk factor does not use any information on exchange rates, it has explanatory power for the cross-section of currency excess returns. This is consistent with our model. However, it cannot replace  $HML_{FX}$  as the pricing factor. In a horse race between these two risk factors,  $HML_{FX}$  drives out innovations to the volatility factor. We have shown that  $HML_{FX}$  extracts the common component of the stochastic discount factors directly from currency

returns; since the global volatility factor is not observed directly but has to be estimated, it is not surprising that  $HML_{FX}$  has superior explanatory power for returns. As a robustness check, we sort countries on their global equity volatility betas (as we did for  $HML_{FX}$  betas). Again, we obtain a clear cross-section of interest rates and currency excess returns. Countries that load more on global volatility offer higher excess returns because they bear more  $HML_{FX}$  risk.

## 5 Conclusion

By sorting currencies by their interest rates, we identify a slope factor in currency returns, driven entirely by common exchange rate variation among different currencies. The higher the currency's interest rate, the more the currency is exposed to this slope factor. This suggests a standard APT approach to explaining carry trade returns. The loadings on this slope factor line up with the average returns on the currency portfolios.

Furthermore, we derive conditions under which a standard affine model can replicate these carry trade returns. Heterogeneity in the loadings on a common component in each country's SDF is critical. In times of heightened volatility of the common innovations to the SDF, lower interest rate currencies endogenously become more exposed to the common innovations and hence they offer insurance, because their exchange rate appreciates in case of an adverse global shock. In addition, we can recover similar patterns in interest rates and currency returns by sorting currencies into portfolios based on their exposure to the carry trade risk factor and to a measure of global volatility in equity markets, not using any interest rate information whatsoever. This suggests that the common variation in exchange rates that we have uncovered after sorting currencies by their interest rates is not a statistical artifact produced by sorting the currencies by their interest rates but instead truly measures differences in exposure to global risk. While we cannot conclusively disprove them, our work raises the bar for other candidate explanations.

## Notes

<sup>1</sup>This literature includes world arbitrage pricing theory (developed by Adler and Dumas (1983) and Solnik (1983)), a world consumption-CAPM (Wheatley (1988)), a world CAPM (Harvey (1991)), world latent factor models (Campbell and Hamao (1992), Bekaert and Hodrick (1992) and Harvey, Solnik and Zhou (2002)), world multi-beta models (Ferson and Harvey (1993)), and more recently work on time-varying capital market integration by Bekaert and Harvey (1995) and Bekaert, Hodrick and Zhang (2009).

<sup>2</sup>In earlier work, Bekaert (1996) and Bansal (1997) had pointed out the need for heteroscedastic pricing kernels in order to produce time-varying currency risk premia.

<sup>3</sup>In closely related work, Brandt et al. (2006) infer the need for a large common component in the pricing kernel from the high Sharpe ratios in equity markets and the low volatility of exchange rates. Colacito and Croce (forthcoming) deliver a general equilibrium dynamic asset pricing model with this feature.

<sup>4</sup>Hodrick (1987) and Lewis (1995) have surveyed this literature. Bansal and Dahlquist (2000) show that UIP works better for exchange rates of countries that have experienced higher rates of inflation.

<sup>5</sup>Bansal and Dahlquist (2000) were the first to examine the cross-sectional relation between interest rates and currency risk premia. They document that the Hansen and Hodrick (1980) and Fama (1984) findings seem to apply mostly to developed economies.

<sup>6</sup>Jones (2009) offers this example to illustrate the size of the implied returns at the peak of these CIP deviations: “Assuming that USD funds were available, the arbitrageur would attempt to borrow \$1m dollars at 12-month USD LIBOR and enter into a foreign exchange swap to Euros to invest the funds for an identical term in Euro Libor. On completion of the swap and repayment of the loan, the arbitrageur will be left with approximately \$12,600 (126bp) profit.” We can safely regard a return of 126 basis points in one of the 26 years of our sample as measurement error. Taking this into account would change the average return by around 5 basis points.

<sup>7</sup>We compute real interest rates as nominal interest rates minus expected inflation. We use the lagged one-year change in log consumer price index as proxy for expected inflation. For some countries in the developing group, we have no consumer price index data. This is the case for Kuwait, Saudi Arabia, and United Arab Emirates. The data for Turkey starts in May 1986. The data for South Africa starts in January 2008.

<sup>8</sup>Our asset pricing tables report two  $p$ -values: in Panel I, the null hypothesis is that all the

cross-sectional pricing errors are zero. These cross-sectional pricing errors correspond to the distance between the expected excess return and the 45-degree line in the classic asset pricing graph (expected excess return as a function of realized excess returns). In Panel II, the null hypothesis is that all intercepts in the time-series regressions of returns on risk factors are jointly zero. We report  $p$ -values computed as 1 minus the value of the chi-square cumulative distribution function (for a given chi-square statistic and a given degree of freedom). As a result, large pricing errors or large constants in the time-series imply large chi-square statistics and low  $p$ -values. A  $p$ -value below 5% means that we can reject the null hypothesis that all pricing errors or constants in the time-series are jointly zero.

<sup>9</sup>Results available in the separate appendix.

<sup>10</sup>Unconditional betas at the level of portfolios approximate conditional betas for individual currencies to the extent that covariation between conditional means of exchange rate changes and factors is small.

<sup>11</sup>Finally, we also double-sorted by forward discounts (3 bins) and betas (2 bins), and we found that there was no significant spread in betas/returns to be generated. This is not surprising, if, as is the case in our model, interest rates measure the currency's exposure to the common risk factor, and the betas are measured with error.

<sup>12</sup>The detailed results are reported in the separate appendix.

<sup>13</sup>For example, Ferson and Harvey (1999) use both the rolling window and the linear instrumental variable approaches to estimate dynamic factor loadings; see numerous references therein.

<sup>14</sup>Papers that attribute the failure of UIP to systematic risk exposures includes recent papers by Backus et al. (2001), Harvey et al. (2002), Brennan and Xia (2006), Lustig and Verdelhan (2007), Bansal and Shaliastovich (2010), Farhi and Gabaix (2010), Colacito (2008), Alvarez, Atkeson and Kehoe (2009), and Verdelhan (2010). Earlier work includes Korajczyk (1985), Cumby (1988), Bekaert and Hodrick (1992), Bekaert (1996), and Bansal (1997).

<sup>15</sup>When  $\delta$  is identical at home and abroad, the change in the exchange rate is:

$$\Delta q_{t+1}^i = \chi(z_t^i - z^i) + \left( \sqrt{\gamma z_t^i} u_{t+1}^i - \sqrt{\gamma z_t} u_{t+1}^i \right).$$

The real interest rate differential is given by:

$$r_t^i - r_t = \left( \chi - \frac{1}{2}(\gamma + \kappa) \right) (z_t^i - z_t).$$

Hence, the real UIP slope coefficient for a country with the same  $\delta$  as the domestic one is given by:

$$\frac{\chi \left( \chi - \frac{1}{2}(\gamma + \kappa) \right) \text{var}(z_t^i - z^i)}{\left( \chi - \frac{1}{2}(\gamma + \kappa) \right)^2 \text{var}(z_t^i - z^i)} = \frac{\chi}{\left( \chi - \frac{1}{2}(\gamma + \kappa) \right)}.$$

<sup>16</sup>If the Feller condition  $2(1 - \phi)\theta/\sigma^2 > 1$  is satisfied, then there exists a unique positive solution to the equation defining the volatility process  $z$  in the continuous-time limit (Feller, 1951).

<sup>17</sup> In the restricted model ( $\kappa = 0$ ), the entire carry trade premium is due to permanent differences in that version of the model. However, in the full model, part of the carry trade premium is due to transitory differences;  $\kappa$  governs the ‘transitory’ fraction of the carry trade risk premium, because it measures the sensitivity of the price of global risk to local risk aversion.

*Notes:* This table reports, for each portfolio  $j$ , the average change in log spot exchange rates  $\Delta s^j$ , the average log forward discount  $f^j - s^j$ , the average log excess return  $rx^j$  without bid-ask spreads, the average log excess return  $rx_{net}^j$  with bid-ask spreads, the average return on the long short strategy  $rx_{net}^j - rx_{net}^1$  and  $rx^j - rx^1$  (with and without bid-ask spreads), the real interest rate differential  $r^j - r$ , and the portfolio turnover. Log currency excess returns are computed as  $rx_{t+1}^j = -\Delta s_{t+1}^j + f_t^j - s_t^j$ . All moments are annualized and reported in percentage points. Standard errors are reported between brackets. For excess returns, the table also reports Sharpe ratios, computed as ratios of annualized means to annualized standard deviations. The portfolios are constructed by sorting currencies into six groups at time  $t$  based on the one-month forward discount (i.e nominal interest rate differential) at the end of period  $t - 1$ . The first portfolio contains currencies with the lowest interest rates. The last portfolio contains currencies with the highest interest rates. Panel I uses all countries, panel II focuses on developed countries. Data are monthly, from Barclays and Reuters (Datastream). The sample period is 11/1983–12/2009.

*Notes:* This table reports, for each portfolio  $j$ , the average log excess return  $rx^j$  without bid-ask spreads, the average log excess return  $rx_{net}^j$  with bid-ask spreads, the average net return on the long short strategy  $rx_{net}^j - rx_{net}^1$  and  $rx^j - rx^1$ , and the real interest rate difference  $r^j - r$ . Log currency excess returns are computed as  $rx_{t+1}^j = -\Delta s_{t+1}^j + f_t^j - s_t^j$ . All moments are annualized and reported in percentage points. For excess returns, the table also reports Sharpe ratios, computed as ratios of annualized means to annualized standard deviations. In the top panel, the portfolios are constructed by sorting currencies into six groups at time  $t$  based on the *average* one-month forward discount (i.e nominal interest rate differential) *over the first half of the sample* (11/1983–12/1994). The first portfolio contains currencies with the lowest average interest rates. The last portfolio contains currencies with the highest average interest rates. In the bottom panel, the portfolios are constructed by sorting currencies on current one-month forward discounts. Panel I uses all countries, panel II focuses on developed countries. Data are monthly, from Barclays and Reuters (Datastream). The sample period is 1/1995–12/2009.

6	−0.10 [0.50]	0.61 [0.02]	1.05 [0.03]	93.84										
<i>All</i>					6.79	34.05%					2.63	75.64%		

*Notes:* The panel on the left reports results for all countries. The panel on the right reports results for the developed countries. Panel I reports results from GMM and Fama-McBeth asset pricing procedures. Market prices of risk  $\lambda$ , the adjusted  $R^2$ , the square-root of mean-squared errors  $RMSE$  and the  $p$ -values of  $\chi^2$  tests on pricing errors are reported in percentage points.  $b$  denotes the vector of factor loadings. Excess returns used as test assets and risk factors take into account bid-ask spreads. All excess returns are multiplied by 12 (annualized). Shanken (1992)-corrected standard errors are reported in parentheses. We do not include a constant in the second step of the FMB procedure. Panel II reports OLS estimates of the factor betas.  $R^2$ s and  $p$ -values are reported in percentage points. The standard errors in brackets are Newey and West (1987) standard errors computed with the optimal number of lags according to Andrews (1991). The  $\chi^2$  test statistic  $\alpha'V_\alpha^{-1}\alpha$  tests the null that all intercepts are jointly zero. This statistic is constructed from the Newey-West variance-covariance matrix (1 lag) for the system of equations (see Cochrane (2005), p. 234). Data are monthly, from Barclays and Reuters in Datastream. The sample period is 11/1983–12/2009. The alphas are annualized and in percentage points.

*Notes:* This table reports, for each portfolio  $j$ , the average change in the log spot exchange rate  $\Delta s^j$ , the average log forward discount  $f^j - s^j$ , the average log excess return  $rx^j$  without bid-ask spreads and the average returns on the long short strategy  $rx^j - rx^1$ . The left panel uses our sample of developed and emerging countries. The right panel uses our sample of developed countries. Log currency excess returns are computed as  $rx_{t+1}^j = -\Delta s_{t+1}^j + f_t^j - s_t^j$ . All moments are annualized and reported in percentage points. Standard errors are reported between brackets. For excess returns, the table also reports Sharpe ratios, computed as ratios of annualized means to annualized standard deviations. Portfolios are constructed by sorting currencies into six groups at time  $t$  based on slope coefficients  $\beta_t^i$ . Each  $\beta_t^i$  is obtained by regressing currency  $i$  log excess return  $rx_t^i$  on  $HML_{FX}$  on a 36-period moving window that ends in period  $t - 1$ . The first portfolio contains currencies with the lowest  $\beta$ s. The last portfolio contains currencies with the highest  $\beta$ s. We report the average pre-formation beta for each portfolio. The last panel reports the post-formation betas obtained by regressing realized log excess returns on portfolio  $j$  on  $HML_{FX}$  and  $RX_{FX}$ . We only report the  $HML_{FX}$  betas. The standard errors are reported in brackets. Data are monthly, from Barclays and Reuters (Datastream). The sample period is 11/1983–12/2009.

Table VI: Country-Level Asset Pricing

$\lambda_{HMLFX}$	$\lambda_{RX}$	$b_{HMLFX}$	$b_{RX}$	$R^2$	$RMSE$	$MAPE$	$\chi^2$
Panel I: Developed Countries							
<i>Unconditional Betas</i>							
3.69 [2.31]	2.93 [1.76]	3.90 [2.47]	3.70 [2.25]	59.55	1.11	0.86	36.10
<i>Unconditional and Conditional Betas using Managed Currency Excess Returns</i>							
3.65 [2.20]	2.94 [1.76]	3.85 [2.34]	3.71 [2.25]	75.53	1.17	0.88	39.85
<i>Conditional Betas using Rolling Windows</i>							
3.30 [2.05]	2.43 [1.76]	3.49 [2.19]	3.06 [2.24]	84.19	0.69	0.57	36.84
<i>Conditional Betas using Forward Discounts</i>							
3.96 [2.50]	2.92 [1.71]	4.18 [2.66]	3.68 [2.18]	31.70	1.45	1.08	34.73
Panel II: All Countries							
<i>Unconditional Betas</i>							
3.40 [2.53]	2.54 [1.38]	4.04 [3.15]	5.04 [2.89]	48.29	2.85	1.88	42.36
<i>Unconditional and Conditional Betas using Managed Currency Excess Returns</i>							
4.78 [2.44]	2.69 [1.38]	5.74 [3.03]	5.25 [2.89]	51.51	2.67	1.62	41.77
<i>Conditional Betas using Rolling Windows</i>							
4.64 [1.99]	2.34 [1.35]	5.59 [2.47]	4.54 [2.82]	65.76	2.21	1.48	37.84
<i>Conditional Betas using Forward Discounts</i>							
4.43 [1.59]	2.23 [1.28]	5.33 [1.95]	4.33 [2.63]	66.22	2.36	1.82	33.62

*Notes:* The table reports results from Fama-MacBeth asset pricing procedure using individual currency excess returns. Market prices of risk  $\lambda$ , the adjusted  $R^2$ , the square-root of mean-squared errors  $RMSE$ , the mean absolute pricing error  $MAPE$ , and the  $p$ -values of  $\chi^2$  tests on pricing errors are reported in percentage points.  $b$  denotes the vector of factor loadings. Excess returns used as test assets do *not* take into account bid-ask spreads. Risk factors  $HML$  and  $RX$  come from portfolios of currency excess returns that take into account bid-ask spreads.  $HML$  correspond to a carry trade strategy, long high interest rate currencies and short low interest rate currencies.  $RX$  corresponds to the average currency return across all portfolios. All excess returns are multiplied by 12 (annualized). We do not include a constant in the second step of the FMB procedure. The standard errors in brackets are Newey and West (1987) standard errors computed with the optimal number of lags according to Andrews (1991). Data are monthly, from Barclays (panel I) and Barclays and Reuters (panel II) in Datastream. The sample period is 11/1983–12/2009.

Table VII: Calibrating The Symmetric Model

	Moment	Target	
		(Monthly)	(Annualized)
Panel A: 8 Targets – Moments of Real Variables			
$\beta_{UIP}$	$\frac{\chi}{(\chi - \frac{1}{2}(\gamma + \kappa))}$	-0.50	-0.50
$E(r^{US})$	$\theta \left[ \alpha + \left( \chi - \frac{1}{2}(\gamma + \kappa) \right) + \left( \tau - \frac{1}{2}\delta^i \right) \right]$	0.11%	1.37%
$Std(r^{US})$	$\sqrt{\left( \chi - \frac{1}{2}(\gamma + \kappa) \right)^2 var(z^i) + \left( \tau - \frac{1}{2}\delta^i \right)^2 var(z^w)}$	0.15%	0.51%
$\rho(r_t^{US})$	$\phi$	0.95	0.95
$E_{cross} [Std(\Delta q)]$	$\sqrt{2\gamma\theta + 2\chi^2 var(z^i) + o}$	3.13%	10.85%
$Std(m)$	$\sqrt{(\gamma + \delta + \kappa)\theta + \chi^2 var(z^i) + \tau^2 var(z^w)}$	14.43%	50.00%
$E_{cross} [Corr(r_t^{US}, r_t^*)]$	$\left( \tau - \frac{1}{2}\delta^i \right)^2 \frac{Var(z^w)}{Var(r)}$	0.19	0.19
$E(rx_t)$	$\gamma\theta$	0.04%	0.50%
$Feller$	$2(1 - \phi) \frac{\theta}{Var(z^w)}$	20.00	20.00
Panel B: 3 Targets – Moments of Inflation			
$E(\pi^{US})$	$\pi_0 + \eta^w \theta$	0.24%	2.92%
$Std(\pi^{US})$	$\sqrt{(\eta^w)^2 var(z^w) + \sigma_\pi^2}$	0.32%	1.10%
$E_{cross} [R^2]$	$\frac{(\eta^w)^2 var(z^w)}{var(inflation)}$	0.26	0.26
Panel C: Moments of Nominal Variables			
$E(i^{US})$	$\theta \left[ \alpha + \left( \chi - \frac{1}{2}(\gamma + \kappa) \right) + \left( \tau + \eta^w - \frac{1}{2}\delta^i \right) \right] - \frac{1}{2}\sigma_\pi^2$	0.36%	4.29%
$Std(i^{US})$	$\sqrt{\left( \chi - \frac{1}{2}(\gamma + \kappa) \right)^2 var(z^i) + \left( \tau + \eta^w - \frac{1}{2}\delta^i \right)^2 var(z^w)}$	0.18%	0.63%
$E_{cross} [Std(\Delta s)]$	$\sqrt{2\gamma\theta + 2\chi^2 var(z^i) + 2\sigma_\pi^2 + o}$	2.96%	10.25%
$E_{cross} [Corr(i_t^{US}, i_t^*)]$	$\left( \tau + \eta^w - \frac{1}{2}\delta^i \right)^2 \frac{Var(z^w)}{Var(r)}$	0.39	0.46

This table first reports the moments used in the calibration. The first column defines each moment, the second column presents its closed-form expression in the symmetric version of our model, while the last two columns report the monthly and annual empirical values of each moment in our data. The first panel reports moments of real variables: the UIP slope coefficient  $\beta_{UIP}$ , the mean, standard deviation and autocorrelation of the US real interest rate  $r^{US}$ , the average standard deviation of changes in real exchange rates  $\Delta q$ , the standard deviation of the log SDF  $m$ , the average cross-country correlation of real interest rates, the average return  $rx$  of a US investor on currency markets, as well as the Feller coefficient. The second panel reports the mean and standard deviation of US inflation, along with the average  $R^2$  in regressions of each country's inflation on world inflation. The third panel presents moments that are not used in the calibration but implied by the moments described in the first two panels. The third panel thus reports the mean and standard deviation of US nominal interest rates, the average standard deviation of nominal exchange rates, and the average cross-country correlation of nominal interest rates. Note that  $var(z^w) = \frac{\sigma_w^2 \theta}{1 - \phi^2}$  and  $var(z^i) = \frac{\sigma_i^2 \theta}{1 - \phi^2}$ .  $o = 2(\delta + \kappa)\theta - 2E\left(\sqrt{\delta^i z_t^w + \kappa^i z_t^i}\right)\left(\sqrt{\delta^i z_t^w + \kappa^i z_t^i}\right)$  is an order of magnitude smaller than the other terms. Data are monthly, from Barclays (Datastream). The sample runs from 11/1983 to 12/2009. For means and standard deviations, we report annualized values by multiplying their monthly counterparts by 12 and  $\sqrt{12}$  respectively. The other moments are not annualized.

Table VIII: Parameter Values

Pricing Kernel Parameters						
$\alpha$ (%)	$\chi$	$\gamma$	$\kappa$	$\delta^*$	$\underline{\delta}$	$\bar{\delta}$
0.86	2.78	0.65	16.04	12.84	8.35	17.34
Factor and Inflation Dynamics						
$\phi$	$\theta$ (in bp)	$\sigma$ (%)	$\eta^w$	$\sigma^\pi$	$\pi_0$ (%)	
0.92	7.81	0.25	9.41	0.27	-0.49	

This table reports the parameter values for the calibrated version of the full model. All countries share the same parameter values except for  $\delta$ .  $\delta^*$  is the parameter for the home country. These 11 parameters were chosen to match the 11 moments in Table VII. The parameters  $\delta^i$  are linearly spaced on the interval  $[\underline{\delta}, \bar{\delta}]$ .  $\alpha$ ,  $\sigma$  and  $\pi_0$  are reported in percentages.  $\theta$  is reported in basis points.

Table IX: Simulated Moments

<i>Moment</i>	<i>Nominal Values</i>		<i>Real Values</i>	
	Data	Model	Data	Model
Panel I: Time Series Moments – Home Country				
Interest Rates				
$E[r^{US}]$	4.29%	4.74%	1.37%	1.84%
$Std[r^{US}]$	0.63%	0.50%	0.51%	0.41%
$\rho[r^{US}]$	0.98	0.92	0.95	0.92
Inflation				
$E[\pi^{US}]$	2.92%	2.89%		
$Std[\pi^{US}]$	1.10%	1.10%		
$\rho[\pi^{US}]$	0.46	0.27		
Panel II: Cross-Sectional Moments – All Countries				
Interest Rates				
$E_{cross}(E[r])$	5.89%	4.62%	2.53%	1.72%
$E_{cross}(Std[r])$	1.27%	0.50%	0.82%	0.42%
$E_{cross}(\rho[r])$	0.69	0.92	0.54	0.92
$E_{cross}(corr[r^{US}, r^*])$	0.46	0.53	0.19	0.31
Exchange Rates				
$E_{cross}(Std[\Delta q_{t+1}])$	10.25%	12.26%	10.85%	12.19%
$E_{cross}(\beta_{UIP})$	-0.53	-0.46	-0.09	-0.46
$Std_{cross}(\beta_{UIP})$	0.84	0.07	0.90	0.07
Inflation				
$E_{cross}(E[\pi])$	2.90%	2.90%		
$E_{cross}(Std[\pi])$	1.34%	1.10%		
$E_{cross}(\rho[\pi])$	0.22	0.26		
$E_{cross}(R^2)$	0.26	0.31		
Stochastic Discount Factor				
$E_{cross}[Std(m_{t+1})]$		0.53		0.53
$E_{cross}[corr(m_{t+1}^{US}, m_{t+1})]$		0.97		0.97

This table reports the annualized means and standard deviations of nominal and real variables in the data and in the model. The autocorrelations ( $\rho$ ) reported are monthly. In the first section of Panel I, the table presents the mean, standard deviation, and autocorrelation of the risk-free rate in the home country (the US). In the second section of Panel I, the table presents the mean, standard deviation, and autocorrelation of the inflation rate in the home country. In the first section of Panel II, the table reports the cross-sectional average of the mean, standard deviation, autocorrelation and cross-country correlation of the risk-free rates in all countries. In the second section of Panel II, the table reports the cross-sectional average of exchange rates' volatilities and the cross-sectional average and volatility of the UIP slope coefficients. In the third section of Panel II, the table reports the cross-sectional average of the mean, standard deviation, autocorrelation and  $R^2$  of inflation rates. The  $R^2$  corresponds to the share of each country's inflation variance explained by the average inflation rate. In the fourth section of Panel II, the table reports the cross-sectional average of the SDF volatility and of the cross-country correlation of all SDFs.

Table X: Currency Portfolios - Simulated data

<i>Portfolio</i>	1	2	3	4	5	6
Panel I: Sorting on Current Forward Discounts						
Spot change: $\Delta s^j$						
<i>Mean</i>	0.52	0.03	-0.20	-0.24	-0.38	-0.66

<i>Std</i>	1.11	1.06	1.05	1.04	1.05	1.08
Excess Return: $rx^j$						
<i>Mean</i>	-3.39	-1.65	-0.66	0.06	0.87	2.52
<i>Std</i>	10.86	9.47	8.97	8.82	8.80	9.34
<i>SR</i>	-0.31	-0.17	-0.07	0.01	0.10	0.27
High-minus-Low: $rx^j - rx^1$						
<i>Mean</i>		1.74	2.73	3.45	4.26	5.91
<i>Std</i>		6.64	7.48	8.48	9.53	12.27
<i>SR</i>		0.26	0.36	0.41	0.45	0.48
Average real interest rate difference: $r^j - r$						
<i>Mean</i>	-2.87	-1.62	-0.86	-0.18	0.49	1.86
<i>Std</i>	1.11	1.06	1.05	1.04	1.05	1.08
Turnover						
<i>Trades/currency</i>	0.21	0.45	0.52	0.53	0.51	0.13
Panel II: Sorting on Average Forward Discounts						
Forward Discount: $f^j - s^j$						
<i>Mean</i>	-1.99	-1.44	-0.85	-0.21	0.46	1.41
<i>Std</i>	1.18	1.16	1.14	1.14	1.15	1.12
High-minus-Low: $rx^j - rx^1$						
<i>Mean</i>		0.68	1.24	1.82	2.54	3.48
<i>Std</i>		5.57	5.82	6.34	7.12	7.89
<i>SR</i>		0.12	0.21	0.29	0.36	0.44
Average real interest rate difference: $r^j - r$						
<i>Mean</i>	-1.99	-1.44	-0.85	-0.21	0.46	1.41
<i>Std</i>	1.18	1.16	1.14	1.14	1.15	1.12

Notes: Panel I of this table reports, for each portfolio  $j$ , the average change in log spot exchange rates  $\Delta s^j$ , the average log forward discount  $f^j - s^j$ , the average log excess return  $rx^j$  and the average return on the long short strategy  $rx^j - rx^1$ . All these moments are defined as in Table I. The portfolios are constructed by sorting currencies into six groups at time  $t$  based on the one-year forward discount (i.e nominal interest rate differential) at the end of period  $t - 1$ . The first portfolio contains currencies with the lowest interest rates. The last portfolio contains currencies with the highest interest rates. All data are simulated from the model. Panel II of this table reports, for each portfolio  $j$ , the average return on the long short strategy  $rx^j - rx^1$ , the average log forward discount  $f^j - s^j$ , and the average real interest rate difference:  $r^j - r$ . The portfolios are constructed by sorting currencies into six groups at time  $t$  based on the average one-year forward discount (i.e nominal interest rate differential) over the entire period. As a result, there is no rebalancing in this case.

Table XI: Time-Varying Betas: Data and Model

	$b_{HML}$	$b_{RX}$	$b_{z \times HML}$	$b_{z \times RX}$
Panel I: Developed Countries				
	0.07	0.85	0.26	0.06
<i>Robust</i>	[ 0.05]	[ 0.09]	[ 0.08]	[ 0.04]
<i>NW</i>	[ 0.02]	[ 0.02]	[ 0.02]	[ 0.02]
Panel II: All Countries				
	0.07	1.01	0.31	0.02
<i>Robust</i>	[ 0.04]	[ 0.09]	[ 0.06]	[ 0.06]
<i>NW</i>	[ 0.02]	[ 0.02]	[ 0.03]	[ 0.03]
Panel III: Simulated data				
	0.08	1.00	0.35	-0.01
<i>Robust</i>	[ 0.01]	[ 0.00]	[ 0.01]	[ 0.00]
<i>NW</i>	[ 0.00]	[ 0.01]	[ 0.00]	[ 0.01]

*Notes:* The table reports results from the panel regressions of excess returns on individual currencies on the risk factors scaled with the currency-specific forward discounts. The excess returns used as test assets do *not* take into account bid-ask spreads. Risk factors *HML* and *RX* come from portfolios of currency excess returns that do take into account bid-ask spreads. *HML* correspond to a carry trade strategy, long high interest rate currencies and short low interest rate currencies. *RX* corresponds to the average currency return across all portfolios. All excess returns are multiplied by 12 (annualized).  $z_t^i$  is the country-specific forward discount rescaled to have a cross-sectional mean of 0 and standard deviation of 1 at any time  $t$ . The standard errors in brackets are robust with clustering by month and currency (*Robust*) or Newey and West (1987) with 2 lags (*NW*). Data are monthly, from Barclays (panel I) and Barclays and Reuters (panel II) in Datastream. The sample period is 11/1983–12/2009.

Table XII: Asset Pricing — With Characteristics

Panel I: Data											
	All Countries						Developed Countries				
	$\lambda_{HML_{FX}}$	$\lambda_{RX}$	$\lambda_{FD}$	$R^2$	$RMSE$	$p - val$	$\lambda_{HML_{FX}}$	$\lambda_{RX}$	$\lambda_{FD}$	$R^2$	$RMSE$
<i>FMB</i>	-4.87	1.82	0.88	70.55	0.82		-7.44	-2.28	1.47	47.07	0.64
	[5.22]	[1.64]	[0.54]			10.15	[10.97]	[3.73]	[1.52]		16.92
Panel II: Simulation											
	$\lambda_{HML_{FX}}$	$\lambda_{RX}$	$\lambda_{FD}$	$R^2$	$RMSE$	$p - val$					
<i>FMB</i>	-1.28	1.24	1.48	97.15	0.27						
	[8.26]	[2.54]	[1.79]			90.02					

*Notes:* This table reports results from a Fama-McBeth asset pricing procedure with characteristics: the average interest rate differential in each portfolio is added to the second stage of the Fama-McBeth estimation. Market prices of risk  $\lambda$ , the adjusted  $R^2$ , the square-root of mean-squared errors  $RMSE$  and the  $p$ -values of  $\chi^2$  tests on pricing errors are reported in percentage points. The first panel uses actual data. Excess returns used as test assets and risk factors take into account bid-ask spreads. Data are monthly, from Barclays and Reuters in Datastream. The sample period is 11/1983–12/2009. The second panel uses the last 300 periods of simulated data. All excess returns are multiplied by 1200 (i.e., in percent, annualized). We do not include a constant in the second step of the FMB procedure.

Table XIII: Asset Pricing - Equity Volatility Risk Factor (Innovations)

Panel I: Factor Betas						
<i>Portfolio</i>	All Countries			Developed Countries		
	$\beta_{Vol_{Equity}}^j$	$\beta_{RX}^j$	$R^2$	$\beta_{Vol_{Equity}}^j$	$\beta_{RX}^j$	$R^2$
1	0.37 [0.12]	1.04 [0.05]	74.78	0.58 [0.25]	0.99 [0.06]	72.55
2	0.22 [0.10]	0.94 [0.04]	76.21	0.16 [0.14]	1.01 [0.04]	80.01
3	0.19 [0.10]	0.95 [0.04]	74.34	0.20 [0.13]	1.04 [0.03]	86.67
4	0.13 [0.08]	0.95 [0.05]	75.44	-0.35 [0.18]	0.97 [0.04]	82.02
5	-0.10 [0.13]	1.06 [0.05]	76.30	-0.59 [0.16]	0.99 [0.05]	74.50
6	-0.81 [0.16]	1.07 [0.06]	63.84			
Panel II: Risk Prices						
	All Countries			Developed Countries		
	$\lambda_{Vol_{Equity}}$	$\lambda_{RX}$	$R^2$	$\lambda_{Vol_{Equity}}$	$\lambda_{RX}$	$R^2$
<i>FMB</i>	-4.20 [1.41] (1.65)	1.33 [1.35] (1.35)	66.10	-2.31 [1.46] (1.53)	1.91 [1.73] (1.73)	48.12

*Notes:* The panel on the left reports empirical results using actual data for all countries. The panel on the right reports results for the simulated data from the calibrated model. Panel I reports OLS estimates of the factor betas. Panel II reports risk prices from the Fama-MacBeth cross-sectional regression. Market prices of risk  $\lambda$  and adjusted  $R^2$ s are reported in percentage points. Excess returns used as test assets and risk factors take into account bid-ask spreads. All excess returns are multiplied by 12 (annualized). To build our volatility factor, we first compute the standard deviation over one month of daily MSCI changes for each country in our sample. We then compute the cross-sectional mean of these volatility series. Our risk factor corresponds to volatility innovations, obtained as log differences of our global volatility series. We do not include a constant in the second step of the FMB procedure. The sample period is 11/1983–12/2009. The standard errors in brackets are Newey and West (1987) standard errors computed with the optimal number of lags according to Andrews (1991). Shanken (1992)-corrected standard errors are reported in parentheses.

## Abstract

In this separate appendix, we first report in Section 1 the asset pricing results obtained with the first principal components of our currency portfolios. We then check in Section 2 that our betas are driven by exchange rate changes, not interest rate variations. Section 3 reports an additional robustness check: we split the sample of countries in two groups and show that risk factors built using currencies that do not belong to the portfolios used as test assets can still price these assets. Section 4 checks that our two risk factors ( $RX$  and  $HML_{FX}$ ) in the model price the cross-section of simulated portfolios and replicate the asset pricing tests on individual currencies. Finally, Section 5 focuses on portfolios of countries sorted by their global equity volatility betas.

# 1 Principal Components as Asset Pricing Factors

The paper presents our main asset pricing estimates. In this appendix, we first build some intuition for why the second principal component is a good candidate risk factor. Following Cochrane and Piazzesi (2008), we compute the covariance of each principal component with the currency portfolio returns, and we compare these covariances (indicated by triangles) with the average currency excess returns (indicated by squares) for each portfolio. Figure 1 illustrates that the second principal component is the only promising candidate. Its covariance with currency excess returns increases monotonically as we go from portfolio 1 to 6.<sup>1</sup> This is not the case for any of the other principal components. As a result, in the space of portfolio returns, the second principal component is crucial.

[Figure 1 about here.]

We thus can use the two first principal components themselves as risk factors. The results are reported in Table 1. The risk price of the carry factor (the second principal component) is 4.16 % per annum and the risk price of the dollar factor (the first principal component) is 3.46 % per annum. The risk-adjusted return on  $HML_{FX}$  is -21 basis points per annum. The only portfolio with a statistically significant positive risk-adjusted return is the fourth one. However, the null that the  $\alpha$ 's are jointly zero cannot be rejected.<sup>2</sup> All of the statistics of fit are virtually identical to those that we obtained when we used  $HML_{FX}$  and  $RX_{FX}$  as factors.

[Table 1 about here.]

## 2 Exchange Rate Betas

A natural question is whether the unconditional betas of our main asset pricing experiment are driven by the covariance between exchange rate changes and risk factors, or between interest rate changes and risk factors. This is important because the conditional covariance between the log currency returns and the carry trade risk factor obviously only depends on the spot exchange rate changes:

$$cov_t [rx_{t+1}^j, HML_{FX,t+1}] = -cov_t [\Delta s_{t+1}^j, HML_{FX,t+1}].$$

The regression of the log changes in spot rates for each portfolio on the factors reveals that these conditional betas are almost identical to the unconditional ones (with a minus sign), as expected. Table 2 in this appendix shows the currency betas. Low interest currencies

offer a hedge against carry trade risk because they appreciate when the carry return is low, not because the interest rates on these currencies increase. High interest rate currencies expose investors to more carry risk, because they depreciate when the carry return is low, not because the interest rates on these currencies decline. This is exactly the pattern that our no-arbitrage model delivers. Our analysis within the context of the model focuses on conditional betas.

[Table 2 about here.]

### 3 Robustness Check: Splitting Samples

To guard against a mechanical relation between the returns and the factors, we randomly split our large sample of developed and emerging countries into two sub-samples.

To do so, we sort countries alphabetically and consider two groups. Table 3 reports market prices of risk and factor betas. The panel on the left uses countries A to M as test assets; the panel on the right uses countries N to Z as test assets. We use two risk factors: the return on high interest rate minus low interest rate countries and the average return on currency markets. On the left panel, risk factors are built from portfolios of countries N to Z. On the right panel, risk factors are built from portfolios of countries A to M. As a result, test assets and risk factors belong to two non-overlapping sets of countries.

Clearly, risk factors built using currencies that do not belong to the portfolios used as test assets can still explain currency excess returns. However, the market price of risk appears higher and less precisely estimated than on the full sample, and thus further from its sample mean. This happens because, by splitting the sample, we introduce more measurement error in  $HML_{FX}$ . This shrinks the betas in absolute value (towards zero), lowers the spread in betas between high and low interest rate portfolios and hence inflates the risk price estimates. However, portfolio betas increase monotonically from the first to the last portfolio, showing that common risk factors are at work on currency markets.

[Table 3 about here.]

We also bootstrapped the sample-splitting experiment. For each run of the bootstrap, we draw randomly two sub-samples of countries. We build four portfolios on each sub-sample. We use the first set of portfolios as test assets and we build two risk factors out of the second set of portfolios: the dollar and carry trade risk factors. Again, test assets and risk factors belong to two non-overlapping sets of countries. We do not take into account bid-ask spreads. We repeat the estimation 1,000 times. The estimated risk price for  $HML_{FX}$  is

18.11 with a standard deviation of 6, compared to mean of  $HML_{FX}$  of 6.77 with a standard deviation of 1.45. This seems to confirm that splitting the sample introduces more noise in the factors and shrinks the betas.

## 4 Model

In our model, the two asset pricing factors  $RX$  and  $HML_{FX}$  completely explain the cross-sectional variation in average excess returns on the currency portfolios – this is true by construction. For completeness, we report these asset pricing results obtained on simulated data in Table 4. In the cross-sectional asset pricing tests, the estimated market price of the carry trade factor  $HML_{FX}$  is 5.91% per annum, very close to the sample mean. The price of the aggregate market return  $RX$  is -0.38% and not statistically significant. This is due to the fact that we assigned the home country’s pricing kernel an “average” loading on the global risk factor. Due to the cross-sectional heterogeneity in the loadings on the world risk factor, our model is able to reproduce the variation in average returns on currency portfolios, and in particular the large average return on the carry trade factor. The bottom panel in Table 4 reports the loadings of different currency portfolio returns on the two factors. As can be seen from the pattern in the betas, our model reproduces the common factor structure in currency portfolio returns and hence in exchange rates.

[Table 4 about here.]

We also replicate the asset pricing tests on individual currencies. One difference between the simulated and the actual data is that in the model we have a balanced panel whereas in the data some currencies only appear in the sample in the later years, while others disappear over time. Nevertheless, as shown in Table 5, the model closely matches the empirical evidence. The price of carry risk estimated using the cross-sectional Fama-MacBeth regressions using both unconditional and conditional betas is close to the sample mean of the factor, and the model is able to explain roughly 60 – 70% of sample variation in average currency returns.

[Table 5 about here.]

## 5 Global Volatility Betas

As a robustness check, we sort countries on their global equity volatility betas (as we did for  $HML_{FX}$  betas). For each date  $t$ , we first regress each currency  $i$  log change in exchange

rate  $\Delta s^i$  on a constant and  $Vol_{Equity}$  using a 36-month rolling window that ends in period  $t - 1$ . This gives us currency  $i$ 's exposure to  $Vol_{Equity}$ , and we denote it  $\beta_t^{i,Vol}$ . It only uses information available at date  $t$ . We then sort currencies into six groups at time  $t$  based on these slope coefficients  $\beta_t^{i,Vol}$ . In constructing these portfolios, we do not use any information on interest rates. The first portfolio contains currencies with the lowest  $\beta$ s. The last portfolio contains currencies with the highest  $\beta$ s. Table 6 reports summary statistics on these portfolios. The first panel reports average changes in exchange rates. The second panel shows that average forward discounts increase monotonically from the first portfolio to the last portfolio. Again, we have not used any information on exchange rates or interest rates to obtain these portfolios. Yet, they deliver a clear cross-section of interest rates. The third panel reports the average log excess returns. In both samples, they are monotonically increasing. The last three panels report pre- and post-formation betas. Pre-formation betas (obtained over short windows) are more volatile than post-formation betas (obtained over the entire sample). These post-formation volatility betas are not significant, across portfolios and for both samples. However, using  $HML_{FX}$ , the post-formation betas that we obtain over the entire sample are significant, and we recover a monotonic cross-section. Countries that load more on global volatility offer higher excess returns because they bear more  $HML_{FX}$  risk.

Notes: The factors are the first and the second principal components (denoted  $d$ , for the “dollar” factor, and  $c$ , for the “carry” factor, respectively). The panel on the left reports results for all countries. The panel on the right reports results for the developed countries. Panel I reports results from GMM and Fama-McBeth asset pricing procedures. Market prices of risk  $\lambda$ , the adjusted  $R^2$ , the square-root of mean-squared errors  $RMSE$  and the  $p$ -values of  $\chi^2$  tests on pricing errors are reported in percentage points.  $b$  denotes the vector of factor loadings. Excess returns used as test assets and risk factors take into account bid-ask spreads. All excess returns are multiplied by 12 (annualized). The standard errors in brackets are Newey and West (1987) standard errors computed with the optimal number of lags according to Andrews (1991). Shanken (1992)-corrected standard errors are reported in parentheses. We do not include a constant in the second step of the FMB procedure. Panel II reports OLS estimates of the factor betas.  $R^2$ s and  $p$ -values are reported in percentage points. The  $\chi^2$  test statistic  $\alpha'V_\alpha^{-1}\alpha$  tests the null that all intercepts are jointly zero. This statistic is constructed from the Newey-West variance-covariance matrix (1 lag) for the system of equations (see Cochrane (2005), p. 234). Data are monthly, from Barclays and Reuters in Datastream. The sample period is 11/1983–12/2009. The alphas are annualized and in percentage points.

*Notes:* This table reports, for each portfolio  $j$ , the average change in the log spot exchange rate  $\Delta s^j$ , the average log forward discount  $f^j - s^j$ , the average log excess return  $rx^j$  without bid-ask spreads and the average returns on the long short strategy  $rx^j - rx^1$ . The left panel uses our sample of developed and emerging countries. The right panel uses our sample of developed countries. Log currency excess returns are computed as  $rx_{t+1}^j = -\Delta s_{t+1}^j + f_t^j - s_t^j$ . All moments are annualized and reported in percentage points. For excess returns, the table also reports Sharpe ratios, computed as ratios of annualized means to annualized standard deviations. Portfolios are constructed by sorting currencies into five or six groups at time  $t$  based on slope coefficients  $\beta_t^i$ . Each  $\beta_t^i$  is obtained by regressing currency  $i$  log change in exchange rate  $\Delta s_t^i$  on  $Vol_{Equity}$  on a 36-period moving window that ends in period  $t - 1$ . The first portfolio contains currencies with the lowest  $\beta$ s. The last portfolio contains currencies with the highest  $\beta$ s. We report the average pre-formation beta for each portfolio. The last two panels report the post-formation betas obtained by regressing realized log excess returns on portfolio  $j$  on either  $HML_{FX}$  and  $RX_{FX}$ , or  $Vol_{Equity}$  and  $RX_{FX}$ . We only report the  $Vol_{Equity}$  and  $HML_{FX}$  betas. The standard errors are reported in brackets. Data are monthly, from Barclays and Reuters (Datastream). The sample period is 11/1983–12/2009.

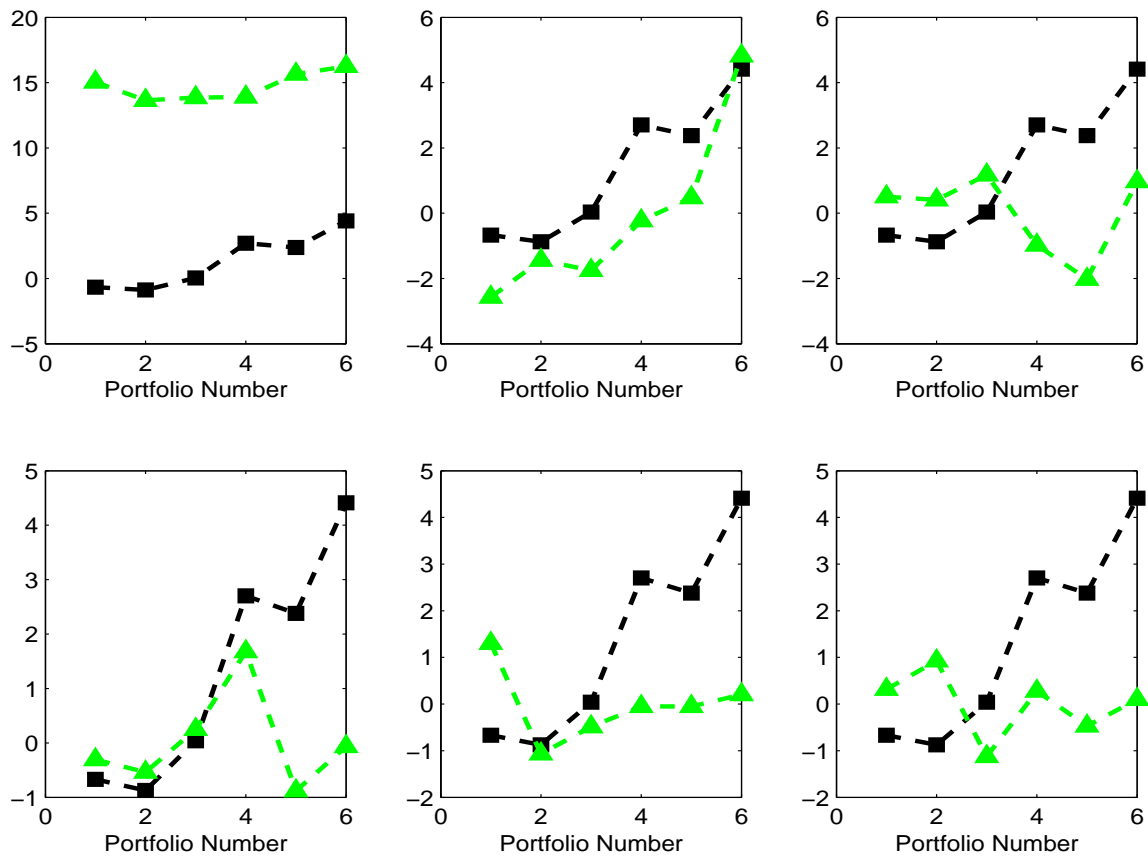

Figure 1: Mean Excess Returns and Covariances between Excess Returns and Principal Components - Developed and Emerging Countries

Each panel corresponds to a principal component. The upper left panel uses the first principal component. The black squares represent the average currency excess returns for the six portfolios. Each green triangle represents a covariance between a given principal component and a given currency portfolio. The covariances are rescaled (multiplied by 15,000). The average excess returns are annualized (multiplied by 12) and reported in percentage points. The sample is 11/1983–12/2009.
